Tensile strength, elongation at break and tear strength decrease, but hardness increases, with increasing ES content from 0 to 75 phr in epoxidized HNR composites (Intharapat *et al.*, 2013). Tensile and tear strength decline because the continuous phase sustains more stress with increasing filler loading. ES-filled epoxidized HNR has higher tear strength, storage modulus and tensile strength, but lower elongation at break, than when commercial calcium carbonate is used (Intharapat *et al.*, 2013). The higher tensile and tear strength are due to the larger surface area of ES particles and stronger covalent bonds formed by oxirane rings of epoxidized NR and the amines of ES. Hardness is similar in ES and calcium carbonate filled HNR and SBR composites (Saeb *et al.*, 2013). The stearic acid coated ES-filled SBR and NR have maximum tensile strength at 5 phr loading, due to the optimal crosslink density at this filler loading (Saeb *et al.*, 2013). However, elongation at break decreases as ES fraction increases, because of the large particle size in this study (Table 6).

Increasing cuttlebone content in HNR composites increases hardness, brittleness and reduces elongation at break, while maximum tensile strength occurs at 20 phr filler loading (Klungsuwan *et al.*, 2013; Poompradub, 2014). Cuttlebone filled HNR has higher tensile strength than commercial calcium carbonate, because of its different filler morphology, even though the particle size of cuttlebone (106 μm) is much larger than commercial calcium carbonate (1.5 μm) (Klungsuwan *et al.*, 2013). The rod-like cuttlebone has more surface area and a stronger filler-rubber interaction than the spherical, commercial calcium carbonate.

At 35 phr filler total loading (CB and ES), tensile strength and elongation at break of GNR composites are maximal with 5 phr ES (average particle size is 23 μm) and 30 phr CB (Barrera and Cornish, 2016a). Increased rubber-ES interaction formed by the hydrophobic components of ES, and the complex shell micro-architecture, may explain these increased mechanical properties. However, tensile strength and 300% modulus slightly reduce with further increasing ES and decreasing CB content (Barrera and Cornish, 2016a). One explanation is that CB has a very small particle size (108 nm) and a non-polar surface (Baranwal and Stephens, 2001; Barrera *et al.*, 2018), which results in a stronger rubber-filler interaction than ES (Barrera and Cornish, 2016a). However, ES filled HNR exhibits different mechanical properties (Barrera and Cornish, 2015) compared to the GNR composites. The modulus at 300% strain and tensile strength of HNR decrease, as ES fraction increases and CB decreases at constant filler loading (Barrera and Cornish, 2015). The various non-rubber components and different rubber macromolecular structure may explain the different reinforcement ability of ES in the two types of NR composites. HNR has a branched structure mediated by proteins and lipid linkages (GNR is linear), and HNR contains considerably more protein than GNR (Tarachiwin *et al.*, 2005; Sarkawi *et al.*, 2013). The branched structure of HNR may impede the establishment of the filler-filler network and reduce rubber-filler interactions (Barrera and Cornish, 2016a). The particle size also affects the ES reinforcement. Both HNR and GNR are more reinforced by micro-sized ES (23 μm) than by macro-sized ES (241 μm) (Barrera and Cornish, 2015, 2016a). However, as the particle size of ES further decreases to nano size (73 nm), the tensile strength, elongation at break and modulus at 300% of the composites are lower than composites made with micro-sized ES, possibly due to nano-ES aggregation (Barrera and Cornish, 2017b).

Application of Waste-Derived Fillers in Rubber Composites

Rubber composites have a variety of applications, which include tires, mats, seals, shoe soles, toys, and many more (Thongsang *et al.*, 2012) and, as mentioned in section “Silica-Based Fillers in Rubber Composites”, some waste-derived filler rubber composites have comparable, or even superior, performance to commercial fillers and a lower cost. Short fiber filled NR composites can be applied to tires (the chafer strip), sole and cord construction (Nair and Joseph, 2014). Tomato peels, ES and carbon fly ash solely filled guayule NR can be applied as rubber tapes (Barrera and Cornish, 2016a). The performance of tire treads, surgical drainage tubes and seals may also be achieved by a hybrid filler of ES and TP filled GNR composites (Barrera and Cornish, 2016a).

Conclusion

Recent progress in research and development of waste fillers in rubber composites has been reviewed in this article. Most waste-derived fillers have potential application in rubber products with the advantage of low cost. Furthermore, silica, cellulose and calcium carbonate based waste fillers improve the mechanical properties of rubber composites, due to uniform filler dispersion, chemical or physical modifications and strong rubber-filler interaction. However, most of the reported studies are still at laboratory scale. Future work, like economic analysis and product design, are needed to develop and commercialize the eco-friendly and reinforcing waste fillers. Waste-derived fillers are expected to open new markets of sustainable rubber products.

Waste Printed Circuit Board (WPCB) Recovery Technology: Disassembly and Desoldering Approach

Muammer Kaya, Eskisehir Osmangazi University, Eskisehir, Turkey

© 2020 Elsevier Inc. All rights reserved.

Introduction

The development of the electronic industry is associated with an increased demand on more precious metals (PMs) and scarce metals (SMs), and increased growth of waste electrical and electronic equipment (WEEE). It is considered to be one of the fastest growing solid waste streams in the world (Sun *et al.*, 2015; Kaya, 2016a). WEEE grows three times faster than the municipal wastes. The final disposal of WEEE is an issue of current worldwide concern. Conventional disposal and incineration methods can pose threats to the whole environment, from the atmospheric to the aquatic and terrestrial compartments. In recent years, recovery of metals from e-waste has become increasingly important due to potential risk of strategic and scarce raw materials and environmental concerns. Half of the e-waste comes from electrical appliances and the rest comes from electronic goods (Kaya, 2016b). In the world, 41.8 Mt e-wastes were produced and 6.5 Mt were formally treated in 2014 (Web 1). In 2016 e-waste amount increased to 44.7 Mt (Web 2). Average e-waste generated per inhabitant was 5.9 kg in 2014 and 6.1 kg in 2016 in the world (Web 1; 2). Proper e-waste management for all countries is necessary; because, e-waste pollutes the ground water, acidifies the soil, generates toxic fume and gas after burning, accumulates fastest in municipal disposal areas and releases carcinogenic substances into the air. E-waste constitutes about 8% of the all municipal waste and contains 40% of Pb and 70% of heavy metals in landfills (Kaya, 2016c).

In order to achieve environmental and metal sustainability in circular economy, green processes need to be developed for the recycling of metals and nonmetals from e-waste (Dodson *et al.*, 2015; Clark *et al.*, 2016; Dodson *et al.*, 2012; Hunt *et al.*, 2015). For example, printed circuit boards (PCBs) are essential components and widely used in different fields such as electric and electronic equipment, information technology (IT), and sensing and control industries (Alippi, 2016; Jin *et al.*, 2016; Hadi *et al.*, 2015; Zeng *et al.*, 2016a,b). WEEE and WPCBs are attractive polymetallic secondary source, referred to as "Urban Mines". WPCBs may contain more than 60 metals, including valuable base metals (BMs) (e.g., Sn, Fe, Cu, Zn, Pb, Al etc.), PMs (Au, Ag etc.), platinum group metals (PGMs) (Pd, Pt, Rh, Ir, Ru etc.), SMs (Te, Ga, Se, Ta and Ge) and hazardous metals (HMs) (e.g., Pb, Hg, Be, Cr⁶⁺, As, Sb, Cd etc.) and hazardous substances (e.g., Brominated flame retardants (BFR), acrylonitrile butadiene styrene (ABS), polyvinyl chloride (PVC) etc.) (Zeng *et al.*, 2017; Chen *et al.*, 2016). Informal recycling of metals from WPCBs, especially in developing countries, has caused serious environmental pollution and human health risks (Yu *et al.*, 2016; Fu *et al.*, 2013; Zeng *et al.*, 2016a,b; Awasthi *et al.*, 2016; Li *et al.*, 2015). Using the "Twelve Principles of Green Chemistry" is the most effective way to solve these issues while at the same time alleviating the shortage of mineral resources (Matus *et al.*, 2012a,b; Sheldon, 2016; O'Connor *et al.*, 2016). Based on the principles of Green Chemistry, many environmentally sound processes have been developed to recover metals from e-waste (Hu *et al.*, 2016; Maât *et al.*, 2016; Singh *et al.*, 2016; Sun *et al.*, 2017; Zeng *et al.*, 2015; Guan *et al.*, 2015). WEEE represents a secondary source of metals that have been mined from natural ore resources, where they are often present at low concentrations. Thus, WEEE recovery for the production of secondary materials needs to be encouraged more now and in the future.

There are four main aims of WPCB/e-waste recovery:

- Take care of hazardous/toxic substances contained in e-waste in an environmentally sound manner while preventing secondary and tertiary emissions.
- Recover valuable raw materials (metals and nonmetals) as effective as possible.
- Create economically and environmentally sustainable businesses (optimize eco-efficiency),
- Consider the social implications and local context of operations (e.g., employment opportunities, available skills and education etc.).

Today in e-waste recovery, material (and metal) centric recycling approach changed to product centric recycling approach.

E-Waste, WPCB and Solder Composition

E-waste, especially a mixture of end-of-life (EoL) electronic products from a variety of sources, is of inherently high complexity in composition, phase and physicochemical properties. WPCBs contain about 40% of metal, 30% of organic resins (plastics) and 30% of ceramics. Bare/unpopulated PCBs represent about 23% of the total WPCBs (Duan *et al.*, 2011). WPCBs

contain many ECs; such as resistors, relays, capacitors, integrated circuits (ICs), chips etc. Therefore, dismantling of ECs from WPCBs is the first and the most important step in recycling chain, which can help to conserve scarce resources, establish the reuse of components and eliminate hazardous materials from the environment (Li *et al.*, 2007). WPCBs include ECs and a bare board, which is a mixture of thermosetting and bromine epoxy resins reinforced with glass fibers and several embedded metals in them. PCBs are essential and common elements of almost all of the electronic systems. PCBs are used to mechanically support and electrically connect ECs using conductive pathways, tracks or signal traces etched from Cu sheets laminated onto a nonconductive substrate. PCBs, which provide interconnection between software and hardware, are found in all EEE. Average PCB amount in e-waste is about 3%–5% and even more in some EEEs, like TV set 7%, computer 19%, mobile phone 21% (Duan *et al.*, 2011). Most recycling approaches practiced can only recover metal contents of PCB scraps to an extent 30% of the total weight. More than 70% of PCB scraps (i.e., nonmetal fraction) cannot be efficiently recycled and recovered and have to be incinerated or landfilled (Li *et al.*, 2004).

WPCBs are in generally scraps, faulty, malfunctioning, redundant and over-capacity products. There are three grades of WPCBs according to values; low, medium and high grades. Hagelüken (2006) used Au content of e-waste for classification. If Au content is less than 50 ppm, it is low grade; if Au content is between 50 and 100 ppm, it is medium grade and if Au content is between 100 and 200 ppm, it is high grade and if Au content is more than 400 ppm, it is very high grade. TV boards (without cathode ray tube (CRTs)), audio scraps, calculators, power supply units, alkaline batteries, Pb-batteries, phone batteries, Ni-Cd batteries, laptop batteries, laminate off cuts, transformers and heat sinks are low grade WEEEs. Pins, keyboards, PWBs, car electronics, lamps, phosphors, CRTs, ICT wastes, PC boards, laptops, handheld-computers, WEEE fines and edge connectors are medium grade and prices change from 1 to 8 Euros kg⁻¹ and ICs, optoelectronic devices, PCB scraps, mobile phones, NdFeB magnets, multi-layer ceramic capacitors (MLCCs), some boards and main frames are high grade WPCBs and prices change from 8 to 25 Euros kg⁻¹. High grade and high value WPCBs are estimated about 15% of total PCBs (Kellner, 2009). Value of WPCBs changes from 1000 to 25,000 Euros per ton according to grade quality.

Table 1 shows representative material compositions of WPCBs by wt% used in 31 previous studies. (Duan *et al.*, 2011; Chancercel *et al.*, 2009; Kaya, 2016a). These materials can be categorized in three groups: organic materials, metals and ceramics. Bare/unpopulated WPCBs without any ECs and solder represent 65%–70% by weight of an average PCB and easy to recycle to obtain Cu, epoxy resin and glass fiber with some Au, Ni and Cu plating on their surfaces. Yang *et al.* (2017) determined WPCBs from desktop and laptop PCs after central processing unit (CPU) and random access memory (RAM) had been removed. Bare PCB is rich in Cu, Sn and Ag and ECs are rich in Cu, Fe, Sn, Ag and Au (Table 2). Recycling of these metals is becoming more and more important in order to counteract the depletion of scarce mineral resources, especially as demand for these metals continues to increase.

The oldest and most common Pb-based solders used in electronics are 63Sn–37Pb. Table 3 shows solder alloys using in PCB packaging. Melting points of solder alloys are low and change between 176 and 228°C which is important for desoldering ECs from WPCBs. The Sn-Pb alloys, particularly those near to the eutectic composition, are used as solders while the main substrate or leads are made of Cu.

History of E-Waste Recovery

In the past few decades, recycling of WEEE by environment-unfriendly, hazardous and crude primitive technologies in China, India and some Africa countries has increased. Massive amount of dumping, acid leaching or open burning of WEEE took place. Resource reutilization and safe disposal of metals from WEEE has a great environmental protection. In the initial stage of WEEE

Table 1 WPCB material composition

Metals (~ 40%)	(%)	Ceramics (~ 30%)	(%)	Plastics (~ 30%)	(%)
Base metals					
Cu	6–27	SiO ₂	15–30	PE	10–16

Note: Reproduced from Kaya, M., 2016b. Recovery of metals from electronic waste by physical and chemical recycling processes Int. J. Chem. Nucl. Mater. Metall. Eng. 10.

recovery, simple and rough recovery processes were widely adopted. Manual dismantling, wet gravity separation (i.e., shaking tables), strong acid leaching etc. were the first crude WEEE recovery processes. These methods have both low recovery rates and damage the human health and environment. At the beginning of 1970s, mechanical separation methods began to be utilized to treat the WEEE (Zhang and Forssberg, 1997). There are international programs combating e-waste problems today. Transboundary movement of hazardous waste has been banned by Basel Convention since 1989. Japan, the EU and OECD countries adopted laws/directives related to e-waste after 2001. European Innovation Partnership (EIP) on raw materials, ERA-MIN roadmap and UNEP resource panel are activities addressing recycling innovation.

Fig. 1 show both physical properties of metals and plastics in WEEE and potential separation method selection for metals recovery from WEEE. Plastics have specific gravities between 0.9 and 2.0 g cm⁻³. Al is the lightest metal in WEEE. Six metals (Cr, Sn, Fe, Ni, Co and Cu) have a specific gravity between 7 and 9 g cm⁻³. Pb, Ag and Pd have specific gravity between 10 and 12 g cm⁻³ and three metals (W, PGMs and Au) have between 19.3 and 21.4 g cm⁻³. Mechanical recycling steps include selectively dismantling, crushing and physical separation methods in which separation criteria's, possible equipment and separation characteristics are summarized in Table 4 along with advantages and disadvantages. Plastics and glass are non-conductor. Five metals (Pb, Cr, Sn, Fe and Pd) have electrical conductance less than 10; three metals (Ni, Co and Al) have between 10 and 40 and three metals (Au, Cu and Ag) have between 40 and 70*10⁶ m⁻¹ Ω⁻¹. Au, Ag, Pb and Cu metals, plastics and glass are diamagnetic; Pd, Sn, Cr and Al are paramagnetic and Fe, Ni and Co are ferromagnetic metals. Based on these data, plastics and Al metal can be separated from other metals by gravity separation; ferromagnetics (Fe, Ni and Co) can be separated from diamagnetics (plastics, glass, Au, Pb, Ag and Cu) by magnetic separation and metals and Al-Cu can be separated from plastics by electrostatic separation methods.

WPCB Reuse and Recovery Systems

PCBs are always mounted with ECs whereby PCBs without ECs are called bare PBC or printed wiring board (PWB). Most of the ECs are functional and usable at the time of disposal/dismantling. Therefore, dismantling ECs from WPCBs is a crucial step from both standpoints of materials recovery and ECs reuse in the WPCBs recovery chain to conserve scarce resources, reuse functioning ECs,

Fig. 1 Physical properties of metals and plastics in WEEE and potential physico-mechanical separation method selection for metal recovery from e-waste.

Table 4 Physico-mechanical separation methods used in WEEE recycling

Separation method	Separation criteria	Separation equipment	Separation character	Advantages/disadvantages
Gravity separation (GS)	Density difference	Air current separation (ACS) Shaking tables, Jigs, Heavy media separation (HMS)	Separates light plastics/glass from heavy metals	Air velocity, particle size, shape and density affect separation
Magnetic separation (MS)	Magnetic susceptibility	Dry magnetic separation (DMS)	Separates ferrous metals from non-ferrous metals (Al, Cu, Au, Ag etc.)	Suitable for separating Fe, steel, Ni, Cr; but, not suitable separating nonferrous metals
Electrostatic separation (ES)	Electrical conductivity/ density	Eddy current separation (ECS)	Separates ferrous and nonferrous materials	Recover nonferrous metallic particles (Al, Cu) from non- metals (plastic, glass)
	Electrical conductivity	Corona electrostatic separation (CES)	At 0.2–1.2 mm, separates metallic particles from nonmetallic particles	Metals/precious metals from plastic/glass

and eliminate potential exposure to hazardous materials. For example, removal and disposal of toxic (mainly in electrolytes), explosive and combustible materials from Al-electrolytic capacitors (AECs) is essential and crucial in WPCB recovery. AEC also contains up to 50 wt% Al and Fe and worth recovering (Zhang and Forssberg, 1997). Current generic material and component recovery methods are typically combination of the following recycling processes. The recycling chain for e-waste is classified into four main subsequent steps:

Fig. 2 E-waste recycling chain and end-of-life WEEEs/WPCBs treatment options.

- 1st Step: Collection and presorting,
- 2nd Step: Pretreatment (includes dismantling and size reduction for liberation),
- 3rd Step: Preprocessing (includes separation, upgrading and extraction), and
- 4th Step: End processing (purification and refining) (Fig. 2).

Collection of e-waste is of crucial importance as this determines the amount of material that is actually available for recycling. Many collection programs are in place; but, their efficiency varies from place to place and improvements of collection rates depend on more on social and societal factors than on collection methods. WEEE/WPCBs follow four different treatment options: landfill, incineration, shredding and disassembly. Reuse of some ECs can be achieved with only disassembly. Shredding produces products for recycle, incineration and landfill. WEEE/WPCBs can also be disposed by either incineration or landfilling.

Dismantling/Disassembly

Disassembly process employs to segregate ECs and/or materials that are reusable, identifiable or hazardous in such a manner as to maximize economic return and to minimize environmental pollution, enabling subsequent processes to be performed more efficiently and effectively. Disassembly is the systematic removal of ECs, parts, a group of parts or a subassembly from e-waste. Depollution is the removal of toxic or environmentally harmful components/substances containing Pb; Cr⁺⁶; Hg switches/lamps; CRTs; P coatings; NiCd/NiMH/LiOn and Li polymer batteries; de-gassing; oil; polychlorinated biphenyl (PCB) containing capacitors; inks; toners; coolants/refrigerants; CFCs/HCFs in foam etc. and useful/reusable EC materials. The aim of dismantling process is to liberate the materials and direct them to adequate subsequent pre/end- treatment processes. Hazardous substances have to be removed and stored or treated safely while valuable components/materials (WPCBs, HDs etc.) need to be taken out for reuse or to be directed to efficient recovery processes. Dismantling of ECs on WPCBs is the first and the most important step in a recycling chain which can help to conserve scarce resources, establish the reuse of components and eliminate hazardous materials from environment. Disassembly is the major cost element and time consuming operation in recycling technology. Low processing capacities hinders the application of manual disassembly in large scale industrial processes. The development of automatic disassembly process is vital when considering the amount of WPCBs worldwide. The most valuable part of e-waste (i.e., PCBs) can be removed from the devices by manual dismantling and mechanical treatment or a combination of both. Manual removal of PCBs prior to e-waste shredding will prevent losses of PMs and SMs. Manual dismantling holds a dominant position in pre-treatment of WPCBs and has low investment cost, utilizing simple electrical/pneumatic tools and can be done by people with little or low education after appropriate training. Increasing labor cost and low processing capacities are hindering the application of

manual disassembly in large scale industrial processes. Because the labor cost already become the second largest expenditure of EU WEEE plants. Manual or automated disassembly can be performed either partially (selectively) or completely (simultaneously).

Selective disassembly targets out hazardous or valuable components for special treatment. Selective dismantling is generally performed manually and takes a long time. In simultaneous disassembly, entire ECs are evacuated from WPCBs together. Mixed ECs disassembly is good for time saving. Dismantling is performed semi-automatically/automatically. Automated disassembly provides a cost-effective recycle at minimum labor force on a large scale. Radio frequency identification (RFID) tags are very helpful for recognition of ECs on WPCBs (Kellner, 2009). Table 5 summarizes the comparison of manual and automated/semiautomated dismantling methods for e-waste recycling. Automated dismantling has more advantages and less disadvantages than manual dismantling.

Current WPCB dismantling procedures have restrictions on e-waste recycling due to low efficiency and negative impact on environment and human health (Zeng *et al.*, 2013). Therefore, there is a need to seek an environmental-friendly dismantling process. Manual disassembly and sorting are major cost element and high labor burden within any WEEE recycling methodology. The components reuse oriented selective disassembly technology for WPCBs with wet chemical selective desoldering may prevent also environmental pollution and recover expensive solder (contains Sn + Pb).

Although WPCBs are designed for durability of 500,000 h, the average EoL for ECs is 20,000 h, or less than 5% of its designed lifespan. Hence, many ECs are still functioning and usable at the time of disposal as e-waste. Therefore, disassembling ECs from WPCBs is a first and crucial step in WPCBs recovery chain to conserve scarce resources, and eliminate potential exposure to hazardous materials. ECs are usually divided into two parts: functional and usable ECs which could be reused for new products and repairment; and damaged ECs which could be disposed for metals recovery. Large numbers of researches are being focusing on ECs dismantling from WPCBs (Wang and Xu, 2015), mainly processed in two steps (Fig. 3): (1) remove solder joints between base boards and ECs, including wearing down the solder joints on the back-side of WPCBs by grinders (Lee *et al.*, 2012); dissolving the solder by chemical reagents (Haruta *et al.*, 1991); melting the solder by infrared heaters (IR) (Yokoyama, 1997), electronic heating tubes (Ding *et al.*, 2008; Gao *et al.*, 2008), hot air (Pan *et al.*, 2007; Lee *et al.*, 2012) and hot liquids (Guo, 2007; Zhang *et al.*, 2008; Frank, 2002; Zhao *et al.*, 2009) like molten solder, diesel, paraffinic oil and silicon oil; (2) dislodge ECs from WPCBs, including mechanical sweep (Wang *et al.*, 2013), gas jet (Pan *et al.*, 2007; Lee *et al.*, 2012), and centrifugation (Zhou and Qiu, 2010). However, almost all of these technologies could not be applied for industrialization attributed to their various limits, such as low efficiency and high cost.

Undoubtedly, the metal recovery from WPCBs is necessary to the sustainable development of the electronics industry, and many techniques for WPCB dismantling and metals recycling have been developed for the last two decades. Usually, chemical and heating technologies are used for dismantling ECs from WPCBs (Fig. 4). The former faces to the problems of the selection of suitable chemical reagents and their damage to components, which prevents this application in practice. For dismantling ECs and recovering the solder from WPCBs, thermal treatments – such as IR heating, using an electric heating tube, liquid-medium heating, and solder-bath heating – are most commonly used. All these methods generally operate at about 225–265°C which is 40–50°C higher than solder melting point. Critical temperature to generate toxic fumes of WPCBs is 270–280°C (Duan *et al.*, 2011). Because of this heating temperature, dioxin may form during dismantling (Duan *et al.*, 2011; Wang and Xu, 2015; Lee *et al.*, 2012; Zhou and Qiu, 2010; Park *et al.*, 2015). For example, Zeng *et al.* (2013) used water-soluble ionic liquid as a heating medium to dismantle ECs and recover Sn solder from WPCBs, nearly 90% of the ECs were removed from the WPCBs, at 250°C. Simultaneously, an automatic system for disassembling WPCBs with heated air at $265 \pm 5^\circ\text{C}$ was developed by Wang *et al.* (2016). But more energy was consumed by heating WPCBs above the melting point of Sn solder.

Table 5 Comparison of manual and automated/semiautomated dismantling methods

<i>Manual dismantling</i>	<i>Automated/semiautomated dismantling</i>
Advantages	Advantages
● Low investment cost ● Utilize simple tools ● Low educated workers ● Can be performed selectively/simultaneously ● Small scale	● Time saving ● Cost effective ● Minimum labor force ● Large scale ● Semi/full automatic ● Environmental friendly ● Without dust
Disadvantages	Disadvantages
● Takes long times ● Occupational health and safety problems ● Dust exposure ● Bad smell and black fumes ● High labor force ● Expensive ● Informal, banned process	● High investment cost

Fig. 3 WPCB dismantling steps.

Recently, a chemical reagent was used to recover Sn solder from WPCBs. [Yang et al. \(2016\)](#) reported that 99% of Sn could be leached with SnCl_4 and HCl at 60–90°C, and the Sn was then recovered from the purified solution by electro deposition. HBF_4 containing H_2O_2 was used to dissolve Sn solder by [Zhang et al. \(2015\)](#), and almost 100% of the solder was dissolved. Recently, [Zhang et al. \(2017\)](#) reported that a leachant containing methanesulfonic acid (MSA) and H_2O_2 can also selectively dissolve the Sn–Pb solder. Although these techniques were conducted at lower temperatures, new chemical reagents (such as SnCl_4 , HCl, HBF_4 and H_2O_2) were consumed.

Desoldering

Desoldering or solder removal is necessary for dismantling ECs from WPCB assemblies. Currently, informal manual selective dismantling uses chisels, hammers and cutting torches to open solder connections and separate various types of metals and components. Cooking on a wood/coal/electric heated plate and melt solder in order to sell the expensive chips and other recovered ECs to acid strippers for further processing is another manual process. Manual informal dismantling has some disadvantages such as a bad smell, black fumes and being a banned process ([Kaya, 2016a,b](#)). There are two different formal desoldering methods: melting solder by heating (thermal treatment) and leaching solder by chemicals (chemical treatment). Leaching easily generates a large amount of waste acid, alkaline liquid, sludge and water, which cause secondary pollution.

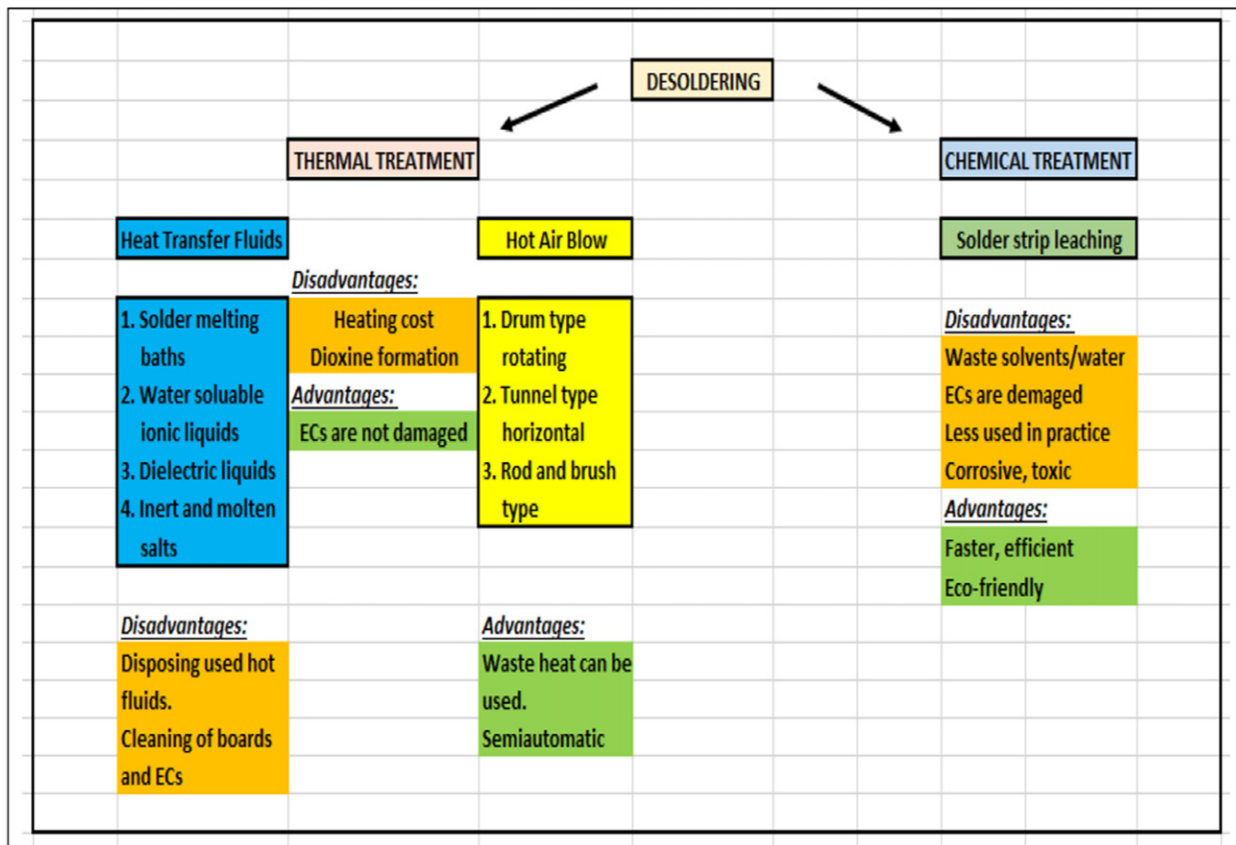

Fig. 4 Thermal and chemical desoldering treatment of WPCBs for disassembly.

Thermal Treatment for Desoldering

In thermal treatment, molten solder baths and different heating elements (i.e., wire/ribbon/strip/tabular resistances made of Nichrome (80/20 NiCr), Kanthal (FeCrAl), Cupronickel (CuNi), ceramic or composite), IR sources, hot air guns, hot air blowers, heat transfer liquids etc. can be used for heating WPCB assemblies for desoldering. Most of the large ECs and surface mount components (SMCs) are dislodged successfully from WPCBs by heating. However, through hole components (THCs) cannot be disassembled although all solder was removed from the WPCBs due to bending of pins under the PCBs and big components with more pins. But, these parts can be removed by a plyer without heating since there is no solder remained on the WPCBs after heating (Wang *et al.*, 2016). Heating method should give minimum damage to the ECs and most of the components should be reused. Heating of WPCBs is performed in a solder melting bath/stove, in a rotating drum dismantling machines, horizontal tunnel furnaces or IR heated lamps (250 W) and brushes. In solder melting baths, electricity is used in heating. When the solder melts, ECs are removed by hitting and shaking the board. Most of the ECs fall from the board. (Fig. 5). Industrial MX-300 melting stoves have a power of 4.0 kW, capacity of 0.4–0.8 tons/h/worker/table and a dimension of 720*500*390 mm (Web 3). One worker works at one tin melting stove table under fume hoods.

Heating with heat transfer liquids (hot fluids)

Bulk heating of WPCBs for desoldering can be achieved in water-soluble ionic liquids, 1-butyl-3-methylimidazolium tetrafluoroborate ((BMIm)BF₄) (Zeng *et al.*, 2013), dielectric liquids, transformer oils, mineral oils, methylphenyl silicon oil and cryogenic liquids (O₂, N₂, H₂, He and Ar). Ninety percent of the ECs were removed from WPCBs at 250°C with water soluble ionic liquids. Inert and stable molten salts (LiCl + KCl (58,2% + 41,8%) and NaOH-KOH eutectic composition (41% NaOH-59% KOH)) can be used as a heat transfer fluid to dissolve glasses, oxides and to destruct plastics present in WPCBs without oxidizing the most of the metals. At 450–470°C range, metal products in either liquid (solder, Zn, Sn, Pb etc.) or solid (Cu, Au, Fe, Pd etc.) form can be recovered. PCB pyrolysis gives 70% solid (metal and glass fiber), 23% oil and about 6% gas product in average (Flandinet *et al.*, 2012; Riedewald and Gallagher, 2015). Disposing the used hot fluid and cleaning of bare boards and components for further processing are disadvantages of using heat transfer fluids. Hot fluids have the disadvantages of generating large quantities of hazardous waste that need to be further disposed and bare boards and components need to be further cleaned (Chen *et al.*, 2013).

Fig. 5 Tin melting baths/stoves layout and operation for ECs dismantling from WPCBs.

Heating with industrial waste heat

Chen *et al.* (2013) used industrial waste heat (i.e., pulsating air jet) to melt solders and separated the ECs from base PCBs. They tested preheat temperatures in increments of 20°C between 80 and 160°C, and incubation times of 1, 2, 4, 6 or 8 min, heating source temperatures ranging from 220 to 300°C in increments of 20°C. The optimum preheat temperature, heating source temperature and incubation time were 120°C, 260°C and 2 min, respectively. The disassembly rate of small SMCs was 40%–50%, and THC and other SMCs were more than 98%. Inlet pressure was 0.5 MPa.

Automatic dismantling machines

WPCB dismantling machines are used to remove the solder and ECs from mixed type WPCB assemblies automatically in e-waste recycling. Thus, labor force is saved and only two people are enough for easy operation. Wang *et al.* (2016) used 245–265°C heating temperature, 2–8 min. incubation time and 6–10 rpm rotating speed for drum type of automated dismantling machine. According to Boks and Tempelman (1998), the main obstacles preventing automatic disassembly of WPCBs from commercially successful are too many different types of products, very small products, general disassembly-unfriendly product design, material logistics problems and control of functioning ECs.

Drum type dismantling machines

The high temperature and abrasion resistant cylindrical drum/barrel is made of steel. This machine works with gas/dust cleaning system or under exhaust hood (Fig. 6). Dismantling machines are safe, reliable and operated easily and have stable performance, high precision and the durability characteristics for WPCB recycling plants. Solder and dismantled ECs without damage are removed in one step by blowing hot air in the drum by a blower. WPCB dismantling machines have automatic temperature control system. Capacities range from 200 to 500 kg h⁻¹, motor power from 2.2 to 3.7 kW and weight from 0.35 to 0.60 tons (Web 4). ECs dismantling rate is claimed as high as 99% without dust in an eco-friendly way. The use of electrical resistances instead of hot air blowers are also possible for heating (Web 5) The off-gas purification with activated carbon is used to avoid hazardous gas discharge to the environment so as to protect workers' health and environment (Wang *et al.*, 2016).

Tunnel type dismantling machines

This system consists of a horizontal solder melting furnace with IR heaters, automated dismantling, dust catching, conveying and panel systems. Higher automation reduces dismantling labor and time. Dust catching prevents dust pollution in the environment. It requires less area in the plant. Dismantling machine technical block flowsheet is given in Fig. 7. From this operation solder, bare PCB assemblies, ECs and dust are collected. Tunnel type dismantling/depopulating machine cross-section details developed in the USA are shown in Fig. 8 (Web 6). 200 kg h⁻¹ capacity dismantling machine has external dimensions (l*w*h) of 8.1*1.6*3.3 m. Total power supply is 15.2 kW and total weight is 1.4 tons. Dust removing efficiency is more than 95% (Web 7).

Rod and brush type disassembly apparatus with IR heater

Park *et al.* (2015) designed and tested automatic rotating rods and sweeping steel brushes type apparatus to dismantle ECs from WPCBs. They used six IR heaters, three rows of rotating six feeding rods and six EC removing steel brushes (Fig. 9). 94% disassembly ratio was obtained at a feeding rate of 0.33 cm s⁻¹ and a heating temperature of 250°C.

Chemical Treatment for Desoldering

Desoldering chemical treatment requires the leaching of Sn and/or Pb to remove ECs on WPCBs. Hydrometallurgical leaching uses various lixiviants/chemicals (such as strong inorganic/weak organic acids, caustic watery solutions, halides etc) to selectively dissolve valuable metals. Chemical leaching is faster and more efficient; however, waste water and waste gas is generated invariably during this process. Hydrometallurgy can be industrially applied to metal recovery for WPCB recycling due to its flexibility, environmental-benign and energy saving features. Its corrosive and poisonous properties require corrosion-proof equipment as well as complicated process operation.

Fig. 6 Automated drum-type WPCB dismantling machine with ECs and solder separating screen (a) along with feed WPCBs (b), bare WPCBs (c) and ECs (d) obtained.

Fig. 7 Tunnel type dismantling machine flowsheet.

Generally, higher lixiviant concentrations and higher temperature enhance leaching rates. A smaller particle size and lower pulp density (solid/liquid (S/L) ratio) are desirable for metal leaching. The particle size can influence the surface area exposed to the leachant. A low S/L ratio indicates that larger volumes of liquid are required. Stirring speed is essentially related to diffusion phenomena, since higher stirring speed usually promotes mass transfer of reactants and reaction products in solution as the diffusion layer at the S/L interface is reduced. Overgrinding should be minimized for economic reasons, since this operation can only be justified to facilitate material handling or for homogenization purposes. Organic acids, which undergo biodegradation and are not evolve toxic gases, are considered as green acids as they are less toxic and corrosive in comparison to inorganic mineral acids.

Solder stripping leach

Several regenerable leaching systems were proposed and tested, e.g., electrogenerated Cl_2 in HCl solution (Kim *et al.*, 2011), $\text{FeSO}_4/\text{H}_2\text{SO}_4$ (Lister *et al.*, 2014), $\text{Fe}_2(\text{SO}_4)_3/\text{H}_2\text{SO}_4$ (Diaz *et al.*, 2016), FeCl_3/HCl (Fogarasi *et al.*, 2013, 2014, 2015), SnCl_4/HCl (for solder stripping) (Jian-guang *et al.*, 2016). Unfortunately, the electrochemical regeneration of chloride based leaching agents

Fig. 9 Rods and brush type ECs disassembly apparatus (on the left); Structure of the disassembly apparatus (on the right).

presents the risk of chlorine evolution, requiring well sealed equipment. Also, the presence of sulfate induces a low rate of the solder alloy dissolution if large amounts of Pb are present. The Br_2 based lixivants can be also used, but some authors suggest that these are unattractive due to the high vapor pressure of Br_2 (28 kPa at 35°C) (Zhang *et al.*, 2012). Contrarily, other researchers

indicate that the use of the adequate complexing agents like bromide or organic ammonium per halides can resolve this problem (Mpinga *et al.*, 2015).

Pb dissolution from solder with HNO_3 oxidizes Pb to PbO which subsequently lead nitrate as given in the following equations:

Sn in solder partially dissolves at low HNO_3 concentrations and form metastannic acid above 4 M HNO_3 concentrations (Mecucci and Scott, 2002). This precipitated metastannic acid dissolves at low HCl concentrations:

Green and strong methanesulfonic acid (MSA) ($\text{CH}_3\text{SO}_3\text{H}$) (pK_a ($-\log K_a$): 1.9 and low molecular weight: 96 g/mol) biodegrade by forming CO_2 and sulfate and leaches solder along with oxidant H_2O_2 (Zhang *et al.*, 2017). Thus, 3.5 M MSA + 0.5 M H_2O_2 aqueous system provides environmental-friendly desoldering separation of Sn-Pb alloy for dismantling ECs from WPCBs. MSA is organic, environment friendly, biodegradable, less toxic, less corrosive acid. It also produces no toxic gas. In MSA- H_2O_2 desoldering leaching, H^+ and CH_3SO_3^- are ionized by MSA and the differences of the standard electrode potential between $\text{H}_2\text{O}_2/\text{Sn}$ (1.912 V) and $\text{H}_2\text{O}_2/\text{Pb}$ (1.902 V) are so close that they can be considered to be stripped down easily from the WPCBs with almost the same ratio at room temperature (Batnasan *et al.*, 2018). Moreover, H_2O_2 is relatively stable in the acidic medium, and its final products environmental-friendly, hardly affecting the recycling of the leachant. Thus, MSA- H_2O_2 aqueous solution system can be regarded as green desoldering separation of Sn-Pb alloy for simultaneous dismantling ECs from WPCBs. In MSA + H_2O_2 aqueous system Sn and Pb leached at room temperature in 45 min. with negligible Cu recovery as per following equations:

Dorneanu (2017) used aqueous bromine-bromide (Br_2/KBr) media for preliminary leaching and dismantling of WPCBs. In this electrochemical recycling system, all metallic parts were removed simultaneous with the lixivants regeneration and the partial electrodeposition of the dissolved metals. For dismantling, specific energy consumption was 0.65 kWh kg^{-1} of treated WPCB. After leaching tests, the remaining undissolved parts (fiberglass boards, ECs, plastics etc.) preserve their original shape and structure, allowing an easier consequent separation/classification and a more efficient recycling.

Size Reduction of WPCBs

The reutilization of WPCB is a focused topic in the field of environment protection and resource recycling. Presently, WPCB is mainly processed using physical, chemical and biological methods or combinations of these approaches. Size reduction is one of the key and crucial processes during pretreatment in recycling. Its importance for chemical and biological methods is that the crushing process must make the surface of the resulting particles appropriate for subsequent contact with the chemical or biological medium. Considering physical methods, particle sizes affect the subsequent process efficiencies, such as separation and leaching. In mechanical separation of metallic components from WEEE is easy to accomplish with a smaller particle size and a narrow size distribution (Cui and Forssberg, 2003; Oggunniyi *et al.*, 2009). During PM leaching, the smaller the particle size (due to higher surface area) the higher the leaching efficiency. But, finer sizes cause more dust generation and environmental pollution.

Kellner (2009) stated that WPCB comminution to -5 mm generated 96%–99% metallic liberation. Duan *et al.* (2009) found that most WPCBs were liberated in the 2–5 mm size. 95% liberation was obtained at -1 mm size for WPCBs. Shredding (fragmenting), crushing, pulverizing, grinding and ball milling are relatively traditional methods for reducing particle size. Recently, the use of cryogenics is being tested and it is believed that it could be used for size reduction in the future due to high cost. In this article, only shredding, pulverizing and delamination are covered in detail. Shredding is a process in which feed material is fragmented, ground, ripped or torn into small pieces. Then, shredded materials are granulated into fine particles (3–20 mm) in pulverizes. Leak tightness of size reduction machines and pipelines must be ensured. Dry crushing generates fugitive odor and dust during crushing. Wet impact crushing to -1 mm is possible. This prevents odor and dust problems and then wet gravity separation using Falcon concentrator can be used for metal recoveries (Duan *et al.*, 2009). Wet impact crushing has the advantages of higher crushing efficiency, less over crushing and no secondary pollution. Water can be recycled in the process only a small amount of fresh water need be supplied. Doddiba *et al.* (2016) proposed an underwater explosion method to disassemble the whole mobile phone units; but, since it is not suitable for industrial practice, it will not be covered here.

Shredders

Shredders are size reducing, crushing and volume reducing machines for e-waste. There are three types of industrial shredders; single-shaft, double-shafts and four-shafts (Fig. 10). Low capacity shredders use one motor and some high capacity shredders have two motors. Shredder machines employ a low speed and high torque mechanism at low noise, energy and dust. They have a wide range of applications because they can shred many different materials. Shredders include cutting chamber, bearings and gears, hexagonal shaft, feed hopper, guard, reducer, cushioned torque arm, drive belt, electric/hydraulic motor (s) and electric panel with PLC control, cabinet and base unit. Different kinds of blades are available for different material shredding to ensure durability and flexibility. Rotary knife thickness, shape, sharpness, design and processing sequence are important for high capacity and long lasting. For industrial shredder applications, blade diameters change from 200 mm up to 800 mm and blade thicknesses range from 20 mm to 80 mm. Thicker blades are used for higher diameter blades. As the blade diameter increases the number of blades increase from 16 to 50. Shredder capacities change from 300 to 40,000 kg h⁻¹ and power consumption from 7.5 to 264 kW (Web 8; 9).

Shredders crush material down to 20 mm. In a single-shaft shredder, the number of rotary blades is between 24 and 57; shaft diameter 220 and 350 mm; rotor length 500–2000 mm, rotating shaft speed 75 and 90 rpm, fixed knife 1 and 2; pressure 6 and 12 MPa; crushing capacity between 250 and 400 kg h⁻¹ and 600–1200 kg h⁻¹; feeding caliber/hopper size (l*w) between 550 and 650 mm and 1280 and 1300 mm; motor power outputs 18.5 and 55 kW; mesh size 20 and 40 mm; weight 3.5 and 9.5 tons and dimensions (l*w*h) 3000*1600*2200 mm and 4500*2500*2800 mm. In double-shaft shredders; the number of rotary blades is between 60 and 150; rotating shaft speed 65 and 87 rpm, fixed knife 4 and 8; blade thickness 30 and 75 mm; crushing capacity 500–2000 kg h⁻¹; feeding caliber (l*w) 700–800 mm and 1650 and 2000 mm; motor power: 18.5*2 and 45*2 kW and weight 4.0 and 9.5 tons. Product size changes from 5 to 20 mm. In four-shaft shredders; the number of main/assistant knife rotary diameter is between 150 and 400 mm; feeding caliber (l*w) 1000–800 mm and 2000–1800 mm; rotating speed 25 rpm; main knife 24 and 64 and main power 11*2 and 45*2 kW. Some companies are producing double story/flat double shaft shredders. Double story shredder and pulverizer on a single chassis are available on the market today. A precrushing shredder is accupulated on the same monoblock body with a pulverizer in some industrial equipment (Web 10).

Fig. 10 Industrial scale single-shaft shredder cross-section (a), double-shaft shredder (b) and four-shaft shredder (c) photos.

Hammer Mills (Pulverizers/Granulators)

Granulator machines are designed with high speed, medium inertia, open rotor body for fine grinding, with 2, 3 or 5 hardened steel knives/blades. Granulators can grind material down to 0.185 mm or up to 5 cm in size. Generally resulting particles can vary in size from 3 to 20 mm. Interchangeable qualifying screens with various diameter holes determine the final reduction size. With decibel ratings of less than 65 dB, these units are ideal for placement at individual work stations. Pulverizers may be gravity discharge or pneumatic discharge. Pulverizers are ideal for heavy, hard and abrasive materials. Granulators are sized by the dimensions of the cutting chamber size ($l \times w$), which changes from 20*25 to 40*88 cm. Motor sizes range from 3.7 to 29 kW. Complete systems can include air discharge units or conveyors, and can easily be integrated with existing shredder or grinder systems. Granulators have a smaller footprint than a full sized grinder, but can still handle high volumes of product in the granulation process (Fig. 11) (Web 9). Hammer mills accomplish size reduction by impacting at a rate of typically 7000 rpms and higher (Kellner, 2009).

Hammer mills can be used for grinding scrap Cu wires, WPCBs, metals and plastics. These granulators are used for the sizing of plastics, non-ferrous metals, and heterogeneous materials and enable to reach controlled output size in the recycling process with the use of classifier screens starting from 2 mm diameter. Sizes of the granulators ($l \times w \times h$) change from (1060–1800) * (1700–1800) * (2000) mm; power from 8 to 90 kW and weight from 0.7 to 4.2 tons. Because of the strength and tenacity of WPCB material, much dust and harmful gas could be produced in the process of dry pulverizing at normal temperatures. On the other hand, after very long operation, very high temperatures can develop in the equipment causing melting and jamming of the particles and, hence, reduced efficiency of crushing/pulverizing and environmental pollution too. A way to enhance crushing efficiency and reduce secondary pollution during processing of WPCB is an important problem. One typical method is to cool the WPCB below the embrittlement temperature using liquid nitrogen and then crush it. The high cost of low temperature crushing limits its further industrial application. To achieve high crushing efficiency and to resolve the secondary pollution problems of dust and gas from the crushing process, a wet impacting crusher can be used to perform comminution of WPCB in a water medium (Duan *et al.*, 2009).

Fractionator

The fractionator process technology is a breakthrough or emerging process to recycle metals from e-wastes in a purely mechanical way. The underlying physical principle is to use the different properties of the materials (density, plasticity, ductility etc.) to separate the layers by creating huge accelerations and decelerations. In a fractionator, a composite material (like WPCBs) with heterogeneous composition and size is submitted to a high frequency series of accelerations and decelerations (impacts). The phases of the material react differently due to their heterogeneous densities and plasticities (Web 11). During accelerations (respectively decelerations), the lighter phases tend to go faster (respectively slower), which create shearing forces at the boundaries. Impacts deform the phases in different ways according to their plasticities. The metals, which are ductile, tend to aggregate into compact shapes and the minerals (i.e., fibers) which are brittle be fragmented while the plastics tend to keep their original shape. WPCBs are shredded and granulated to less than 22 mm. During the process, ferrous materials are easily separated by magnetic separation.

Delamination

The series of high frequency impacts are achieved in a fractionator machine which features an annular space between a rotor and a stator equipped with radial tools. Materials are fed from the top and fall by gravity. The high speed rotation of the rotor drives the materials which then impacts with a high frequency the static tools of the stator as shown in Fig. 12 (Web 11).

Fig. 11 Hammer mill cross section (a) with detachable screens (b) and industrial scale pulverizer machine along with dust collection cyclone (c).

Fig. 12 Industrial size fractionator (a) and cross-sectional view (b).

Fig. 13 Mechanical separation with fractionator and fluidized bed separator for delamination.

Fractionation with delamination

At the bottom of the fractionator, metals, plastics, minerals are liberated; but, still need to be separated. The size distribution is much differentiated at the exit of the fractionator. Plastics are found in relatively coarse particle size distributions. Al and Cu metals

are found as very pure granules with sizes between 50 μm and 5 mm. PMs are in the fines sizes. This makes the two stage separation process (by size and density) very efficient. Metals and nonmetals are separated by size. Light (Al) and heavy (Cu) metals are separated by density in a fluidized bed separator (Fig. 13). (Web 11 and 12).

The process generates different output fractions: Several nonmetallic fractions (plastics, resins, fibers, etc.) with sizes, a ferrous fraction, several light metal (typically Al) fractions, several heavy metal (PMs, Cu and Cu alloys, Ni, Pb etc.) fractions and three dust fractions (the 3 stages – Granulator, Fractionator and Separator – are equipped with aspiration systems and filters). This process has been used more than 20 plants built worldwide since 1995 with the previous generation fractionators. Metal recovery rates are claimed to be above 97%, and the output fractions have a high purity. This process is environmentally friendly; due to dry mechanical treatment, low temperature, no gases or fluids and very limited ultimate wastes. This flexible process has a capacity of 3 t h⁻¹ for very wide range of wastes, suitable for very small lots and campaigns. This plant layout has a competitively low capex and opex, high automation with only 2 workers per shift (Web 11 and 12).

Sizing/Classification

Industrial sizing of materials is extensively used, and the types of equipment are many and varied. Screening is generally carried out on relatively coarse material, as the efficiency decreases rapidly with fineness. Fine screens are very fragile, expensive and easily blocked. Screening is generally limited to the material above about 250 μm in size, finer sizing normally being undertaken by classification (Wills, 1988). Industrial screens may be stationary (i.e., grizzly, sieve beld) or moving (i.e., revolving, reciprocating, gyratory, vibrating etc.). Classification is a method of separating mixtures of minerals into two or more products on the basis of the velocity with which the particles fall through a fluid medium. In classification; hydraulic classifiers, hydrosizers, mechanical classifiers, spiral classifiers hydro/air cyclones can be used (Wills, 1988). Round and rectangular deck shaken sieves and drum sifters are used to classify and sort material according to the size. Trommel screens are large-drum shaped devices with a grate-like surface with large openings. Trommels are used to separate very coarse materials from bulk materials such as coarse plastics from finer Al recycled material. Air/water classifiers, cones, rake classifiers or cyclones can also be used for size classification. Cyclones are essentially settling chambers where the effect of gravity has been replaced by centrifugal acceleration.

Conveyor Belts

Belt conveyors transport material between equipment. Conveyor belts in various sizes and configurations with or without cross-belt magnetic separators for removing ferrous fragments from the flowing material stream during a recycling process are used. Industrial conveyor belt length changes between 2.0 and 3.5 m; width between 0.5 and 0.8 m; height between 1.5 and 2.0 m; weight from 120 to 400 kg; roller diameter size from 10 to 17 cm; roller height from 10 to 53 cm and motor power from 0.5 to 1.1 kW.

Filtration Systems

Filtration systems, operating with sleeve filters, offer a full range of solutions for the dedusting of WPCB recycling process improving the air quality and increasing the efficiency of plants. Reliable and robust SM filters can provide air cleaning with control system. Triple dust collector systems (tetra cyclone + air purifying electrostatic precipitator) or pulse dust removal devices are generally used. Dedust system and activated carbon adsorption tower realize no pollution in whole recycling process. Plants are designed with exhaust gas treatment system. In order to avoid exhaust gas and bad smell for the high temperature, plants are equipped with water spray and active carbon absorption system.

Conclusions

The handling of e-waste including combustion in incinerators, disposing in landfill or exporting overseas is no longer permitted due to environmental pollution and global legislations. The problem caused by e-waste increasingly becomes an international issue due to the characteristics of e-waste amount, discarding continuously, high value materials content and most of all pollutants migration. In order to achieve environmental and metal sustainability in circular economy, green processes need to be developed for the recycling of valuable metals and nonmetals from e-waste. WPCBs, which are the core and most valuable part of WEEE due to PM contained, are a dangerous toxic waste; but, at the same time WPCBs are attractive polymetallic secondary source, referred to as "Urban Mines". WPCBs may contain more than 60 metals and some nonmetal substances. Today in e-waste recovery, material (and metal) centric recycling approach changed to product centric eco-efficient recycling approach.

Illegal and crude e-waste recycling techniques (such as dumping, acid leaching or open burning) used in developing countries are not eco-efficient and economical processes today. Current state-of-the art recycling processes are capable of recovering <95% of the in-feed metals. The development of the recovery technologies for WEEE has entered a new stage. The WEEE disposing

technologies have evolved from simple manual disassembly, classification and sorting to high value-added novel utilization technologies (i.e., physico-mechanical separation and pyro/hydrometallurgical processes) after removing the reusable electronic components by thermal and/or chemical desoldering pretreatment. The components reuse oriented selective disassembly technology for WPCBs with wet chemical selective desoldering can both prevent environmental pollution and recover expensive solder (contains Sn + Pb) material along with bare WPCBs which also contain some nonmetals (i.e., resins, and glass-fibers) and some Cu.

A disassembly stage using thermal and/or chemical desoldering is always required to remove both dangerous components and reusable ECs. Disassembly has traditionally been undertaken manually, but newly developed automated systems impact upon future recycling strategies both to maximize cost-effectiveness for low-value component recovery and as an initial stage for recycling approaches to maximize yield of residual intrinsic-material value. Selective dismantling after desoldering, comminution with two step crushing (i.e., shredding to – 20 mm, delamination and/or pulverizing to – 3 mm) and separation are then key points for improving successful further treatments. 95% metal and nonmetal liberation can be achieved at – 1 mm size. Developing new, clean and economical technologies for recycling of complex and heterogeneous WPCBs is significant challenge. A hidden value in the e-waste can be unlocked by both sustainable recovering base/precious/scarc metals and nonmetals from WPCBs. Therefore, processing of the e-waste must optimize recovery of metals and nonmetals, preserve resources, save energy, prevent pollution, generate new jobs, accelerate economy, minimize final waste volume and processing emissions.

Waste Printed Circuit Board (WPCB) Recycling: Conventional and Emerging Technology Approach

Muammer Kaya, Eskisehir Osmangazi University, Eskisehir, Turkey

© 2020 Elsevier Inc. All rights reserved.

Introduction

Disposal and incineration of e-waste can pose threats to the whole environment, from the atmospheric to the aquatic and terrestrial compartments. In recent years, recovery of metals and/or nonmetals from e-waste has become increasingly important due to potential risk of strategic and scarce raw materials and environmental concerns. The useful life of electrical and electronic equipment (EEE) has been shortened as a consequence of the advancement in technology and change in consumer patterns. This has resulted in the generation of large quantities of e-waste that needs to be managed properly. The handling of e-waste including combustion in incinerators, disposing in landfill or exporting overseas is no longer permitted due to environmental pollution and global legislations. Additionally, the presence of BMs and PMs makes e-waste/WPCBs recycling attractive economically. The main purpose of this article is to provide a comprehensive review for conventional and emerging WPCB recycling technologies using physico-mechanical treatment and/or pyrometallurgical process solutions for secondary metal recoveries. WPCB recycling contributes to resource efficiency, access to critical raw materials and innovation.

It is clear that mechanical pretreatment, which includes desolder dismantling stage to remove both dangerous components and reusable ECs, and metal-nonmetal liberation, are frequently required with the aim to improve the valuable metal and/or nonmetal recovery rates. Selective manual dismantling is still in operation despite the attempts to proceed by simultaneous automatic dismantling procedures, which however, need more progress to be really effective. Shredding, crushing, pulverizing and physico-mechanical separation are then key points for improving successful further end treatments.

Here, firstly separation of metals from WPCBs using physico-mechanical preprocessing and then pyrometallurgical routes are critically analyzed. Pyrometallurgical routes are widely used in e-waste recovery industries and comparatively economical and eco-efficient if the hazardous emissions are controlled. In this article; the existing industrial WPCB recycling practices, used equipment types, sizes and capacities are also covered. Industrially, different physico-mechanical and/or metallurgical routes are separately and/or successively used to extract valuable metals from e-waste. Both pyrometallurgical and hydrometallurgical processes are commonly employed to recover BMs and PMs. Here, pyrometallurgical route was described and its advantages and disadvantages are outlined. Finally, insights into e-waste recovery in the World context are presented. The challenges and barriers associated with recovery of the BMs and PMs are highlighted.

Eco-efficient recycling of WEEE/WPCBs is very important. This means achieving the environmental and economic balance in recycling. It entails maximizing both the physical recycling of metals (or other materials) and the revenue obtained, while minimizing the associated environmental burden and total cost. An eco-efficient process also considers the “environmental fingerprint” of materials, i.e., how much negative environmental impact can be saved by recycling, for example, a metal instead of producing it “new” by mining. Due to the considerable (environmental) impact of turning PMs from low grade ores into pure metals, a high overall recycling yield of them has not merely economic benefits, but also substantial ecological advantages. E-waste recovery offers a sustainable solution to WPCB in order to extract reusable metal components while eliminating organic matter as well as all toxic gas and emission. The end product is a high-grade nonferrous metal concentrate which can be directly reintroduced into the marketplace.

Conventional and Emerging Recycling Methods

Table 1 shows the classification of traditional and emerging WEEE/WPBC recycling methods. Incineration, mechanical separation (gravity) and open acid leaching are conventional crude recycling methods. Pyrometallurgy, physico-mechanical separation (gravity/magnetic/electrostatic), hydrometallurgy, electro-chemical, vacuum metallurgical, super critical and other novel technologies are advanced new technologies. Here, traditional technologies, physico-mechanical separation and pyrometallurgical methods are covered and compared in detail. In the metal recovery processes, mixed type of WPCBs are typically crushed, ground and smelted without disassembling the ECs (Lee *et al.*, 2012). Disadvantageously, when WPCBs are ground, only the plastic fraction can be effectively liberated from metals. However, this leads to the recovery of only Cu, Au and Ag metals and loss of low concentration rare metals. These rare metals can only be recovered by hydrometallurgical processes. Therefore, it is imperative that ECs are disassembled in order to recover these valuable and scarce metals.

Conventional Methods for WPCB Recycling

Incineration

In this process, different type of mixed WEEE is burned in the blast/shaft furnace to obtain 75%–85% black Cu. Then, oxidized in converter and later reduced in the anode furnace. Impurities are mostly segregated into the vapor phase and are discharged in the

Table 1 Classification of conventional and emerging methods for WPCB recycling

Conventional methods	Advanced methods
● Incineration (i.e., burning in blast furnace) ● Mechanical separation – Wet gravity separation (i.e., shaking tables) – Dry gravity separation (i.e., zigzag 3-way air classifier) ● Acid leaching (solubilization + purification)	● Pyrometallurgical technology (smelting + converting + refining) ● Physico-mechanical separation (Gravity-magnetic-electrostatic) ● Hydrometallurgical processes – Mild extraction technology – Bioleaching – Biosorption ● Electrochemical technology ● Supercritical technology ● Vacuum metallurgical technology (vacuum evaporation/sublimation) ● Other novel technologies (ultrasonical, mechanochemical technologies)

off gas. Anodic Cu can be purified with H_2SO_4 along with Ni, Zn and Fe (Zhang and Xu, 2016). Thermal methods result in the emission of hazardous chemicals to the atmosphere and water due to the degradation of epoxy and volatilization of metals (including Pb, Sn, As and Ga). These processes are also high energy consumer and require expensive exhaust gas purification systems and corrosion resistance equipment (Chen *et al.*, 2015a).

Mechanical Separation

This process comprises shredding and grinding of the whole mixed e-waste, followed by separation and concentration using dry/wet gravity separators. WPCBs are ground only plastic resin fraction can be effectively liberated from metal fraction and toxic gases are evolved due to temperature increase in the mill. Accordingly, mechanical methods do not result in high recovery rates, especially for PMs. With dry mechanical separation processes, the potential loss of PMs may be high due to liberation problem between metals and plastics. E-wastes are managed without proper handling by informal sectors in under-developed and developing countries. Since the informal sectors cannot invest in high-tech equipment and machines, it is important to provide a more economical, yet environmentally friendly mechanical separation solutions to this problem. Therefore, it is important to provide simple physical material recovery procedures, which can be applicable for informal sectors.

Acid Leaching

Generally, acid leaching technology is technically more exact, predictable and controllable in material extraction from resources and has already been applied in WPCB recycling for almost three decades (Kaya, 2016c; Lee *et al.*, 2012; Baba, 1987). Various lixiviates/solvents (such as strong inorganic acids, caustic watery solutions or halides) are used to selectively dissolve and precipitate metals in leaching. Selectivity and effectiveness of valuable metals are always important in leaching process. Traditionally, inorganic mineral acids ($HCl/H_2SO_4/HNO_3/HClO_4$) can be used for extracting BMs (Cu, Pb, Zn etc.). Aqua regia (AR) can also be used for non-selective and aggressive digestion of base (Cu, Pb, Zn) and precious (Ag, Au) metals from WEEE. The corrosivity towards Cu, Fe and brass have been proposed in the following order: $HNO_3 > H_2SO_4 > HCl$ (Samina *et al.*, 2011). The majority of hydrometallurgical routes for processing WPCBs use H_2SO_4 (cheapest and widely used acid) leaching in the presence of H_2O_2 as oxidizing agent, followed by solution refining. The use of HNO_3 and HCl was also studied extensively; but, because of the environmental regulations and corrosive nature of these leaching agents they are as appropriate as the less hazardous H_2SO_4 (Yang *et al.*, 2011). HNO_3 has the maximum environmental impact (Iannicelli-Zubiani *et al.*, 2017). Generally, higher acid concentrations and higher temperatures enhance leaching rates. A smaller particle size and lower pulp density (S/L ratio) are desirable for metal leaching (Gu *et al.*, 2017). Low S/L ratio indicates that larger volumes of liquid are required. Metal recoveries most of the time is higher than 90%. Leaching time changes from 60 to 180 min. Leaching can be accelerated with the use of mixing and supercritical CO_2 (g) with significantly increased power consumption (Calgaro *et al.*, 2015).

Advanced Methods for WPCB Recycling

Pyrometallurgical Metal Recovery Processes

Pyrometallurgical processes for recovering metals from various waste materials have been used during the last two decades. Smelting in furnaces, incineration, combustion and pyrolysis are typical e-waste recycling processes. The high temperature in furnace or smelter is generated via the combustion of fuel or via electrical heating. Technical hardware includes submerged lance

smelters, rotary furnaces, electric arc furnaces etc. In contrast to WPCBs from computers, monitors and TV boards usually contain massive Fe and Al parts (i.e., cooling elements, transformers, frames etc.) and possibly large condensers. It is recommended to remove these massive parts before sending the remaining boards to the integrated smelter and refinery (ISR) for final processing. Benefits of such a removal are twofold: Firstly, Al and Fe parts can be valorized by sending to appropriate endprocessing facilities. Secondly, the WPCBs freed from these massive parts are relatively upgraded in the Cu and PM contents, which will generate better revenues obtained from smelter. Such state-of-the-art smelters and refineries can extract valuable metals and isolate hazardous substances efficiently. Such recycling facilities can close the loop of valuable metals and reduce environmental impact arising from large quantities of e-waste. Currently, e-waste recycling is dominated (about 70%) by pyrometallurgical routes, whereas the steel industry embraces the ferrous fractions for the recovery of Fe, and the secondary Al industry takes the Al fractions. The metal fractions separated during the preprocessing of e-waste are composed of Fe, Al, Cu, Pb and PMs. Since Fe and Al, Cu and Pb are the main constituents of a typical e-waste, it is logical to send e-waste to smelters that accept Cu/Pb scrap. Currently, Cu and Pb smelters work as e-waste recyclers for the recovery of mixed Pb/Sn, Cu and PMs. In these pyrometallurgical processes, e-waste/Cu-Pb scraps are fed into a furnace, whereby metals are collected in a molten bath and oxides form a slag phase. Cu smelting route is more environmentally friendly and cheaper than Pb smelting route (Khaliq *et al.*, 2014).

Both ferrous and nonferrous smelters need to have state-of-the-art off-gas treatment in place to deal with volatile organic compounds (VOCs), dioxins and furans. Paints, labels, plastics and resins contain significant amount of flame retardants. Painted scrap should be delacquered prior to smelting using appropriate technologies. For treatment of WPCBs, it is utmost importance that smelter is equipped with state-of-art-gas treatment equipment, since otherwise dioxins are formed and emitted. Process gases are cooled with energy recovery and cleaned. A number of technologies are available for destruction or capture of dioxins, furans and other gases, such as adiabatic coolers, scrubbers, bag house/electro filters and catalytic decomposition are used in combination for optimum performance (Gu *et al.*, 2017). Formation of dioxins during smelting can be prevented by sufficiently high temperatures and long retention time in the smelter. Excess heat from off-gas can be used in subsequent processes.

Pyrolysis, which belong to pyrometallurgical route, has some obstacles to limit large scale operations at present: (1) the yields of gas and liquid generated are low that indicate economic effect; (2) further separation is essential for mixture of pyrolysis residues and metals; moreover pyrolysis residues generally contain toxic materials, like PBDD/Furans and PCDD/Furans and should be disposed properly; (3) the further process cleaning, which would lead to more complex of the process and facilities, which is required for the metals obtained from the course of pyrolysis (Wang and Xu, 2015).

The WPCBs and small devices are mixed with catalysts, by-products from nonferrous industries or primary ore and directly (without further size reduction) treated in ISR. Organic components are converted to energy during smelting. Mechanical upgrading other than disassembly, grading and shredding for bulk volume reduction prior to smelting is not undertaken due to inherent yield loss, particularly of PMs. This loss may be typically in the order of 10% but may be much higher (Kellner, 2009).

Metals from WPCBs were separated utilizing two steps microwave heating. Firstly, heating WPCBs to a temperature sufficient to combust the organic materials present, and the metals of low melting point (like Sn and Al) are removed simultaneously; secondly, heating the WPCBs to a higher temperature at which glass formers present in the WPCBs begin to vitrify, and then metals with higher melting points could be recovered from the solidified residues or might be removed at their respective melting points which are below the vitrifying temperature. This approach is highly efficient; however, this recycling technology has not been transferred to industry because of its high economic cost (Jones *et al.*, 2002). In the processing, the crushed scraps are burned in a furnace or in a molten bath to remove plastics, and the refractory oxides form a slag phase together with some metal oxides. Further, recovered materials are retreated or purified by using chemical processing. Energy cost is reduced by combustion of plastics and other flammable materials in the feeding. Soare *et al.* (2016) used a laboratory furnace with microwave field in Ar inert atmosphere to melt WPCBs after comminution (0.5–2.0 cm) at 1000–1200°C for 30 min. A complete separation of the metallic fraction from the organic components was achieved. Multi-component metallic alloy was processed through combined hydrometallurgical and electrochemical methods. Microwave melting presents a series of advantages, such as rapid heating cycles saves about 35% energy compared to conventional melting, and improved process control, no direct contact with the heating materials, the possibility of processing various nonferrous metals containing wastes.

Industrial processes for recovering metals from e-waste are based on combined pyrometallurgical, hydrometallurgical and electrometallurgical routes. Fig. 1 shows pyrometallurgical Cu production layout from primary ores and WPCBs. In pyrometallurgical processes, e-waste is blended with other materials and incorporated into primary/secondary smelting processes (e.g., into Cu or Pb smelters) at 1250°C. Cu smelting is the dominating route for e-waste recycling where PMs are collected in Cu matte or black Cu. In the final stage of Cu production, i.e., the electro refining process, pure Cu metal is produced and the PMs are separated into slimes where they are recovered using hydrometallurgical routes. Currently, various industrial processes are used globally for extracting metals from e-waste, including the Umicore Hoboken (Belgium) ISR facility, the Noranda process in Quebec (Xstrata), Rönnskär smelters in Sweden (Boliden), Kosaka's recycling plant in Japan (DOWA), the Kayser recycling system in Austria and the Metallo-Chimique N.V plants operated in Belgium and Spain. SIMS Recycling Solution in Singapore and Roorkee, and Attero Recycling in India are some other important e-waste recyclers.

In pyrometallurgical processing, generally WEEE firstly dismantled, shredded, ground for size reduction and liberation of components and then, smelted in furnaces (i.e., blast furnace, reverberatory furnace, Imperial smelting furnace, Outokumpu flash smelting, Mitsubishi continuous smelting, Isasmelt/Csiromelt, Noranda, CMT/Teniente, Vanyukov (Russia), Bayia (China), plasma arc furnace etc.) to obtain coarse Cu sulfide/metal ingots. Noranda uses 10%–14% WPCBs and 86%–90% Cu concentrate as feed. The two basic and widely applied smelting processes include flash and bath smelting. The next step is converting process in

Fig. 1 Pyrometallurgical Cu production layout from primary Cu ore and WPCBs.

Cu converter by blowing hot air from tuyeres in order to obtain molten Cu matte (Cu-Fe-S) (35%–70% Cu). This step oxidizes iron sulfide and convert copper sulfide to metallic blister Cu (about 98.5% Cu). The last step is anodic Cu production in a furnace (99.5% Cu). Anodic Cu is refined by electrolysis to obtain 99.99% Cu ingots and PMs are recovered from anodic mud. **Fig. 2** shows schematic diagrams of Rönnskär smelter for Cu production from both ore concentrate and e-waste. [Zhou and Qiu \(2010\)](#) used 12% NaOH as slag-formation material which promotes the effective separation of metals from slag.

Another application for pyrometallurgical process was the plant of Umicore's ISR, which include Cu smelter, Pb blast furnace and PMs and SMs refineries along with H₂SO₄ plant (**Fig. 3**). Umicore has the world's largest waste recycling facility at Hoboken, Belgium at a feeding capacity of 350,000 t y⁻¹ and annual production capacity of over 50 tons of PGMs, 100 tons of Au and 2400 tons of Ag ([Hagelüken, 2006](#); [Khaliq et al., 2014](#)). Umicore planned to expand its production capacity to 500,000 t y⁻¹ ([Scott, 2014](#)). This process mainly focused on recovery of PMs from WEEE including Ag, Au, Pt, Pd, Rh, Ru and Ir. Its procedures include: firstly, WEEE is pretreated (i.e., dismantling, shredding and physical processing) and then the precious metals operations (PMO) are smelted in an IsaSmelt furnace. Almost all other metals are concentrated in the slag after smelting; thirdly, the slag is further treated at the base metals operations (BMO). The base metals are the byproducts from the PMO which are subjected to electrolytic refining to gain high purity BMs, such as Cu ([Le Ret and Briel, 2011](#); [Tuncuk et al., 2012](#)). At Shanghai Xinjinqiao Environmental Co., Ltd. and Yangzhou Ningde Precious Metal Co., Ltd. in China with the capacity of 5000 t y⁻¹ WPCBs; vacuum metallurgical separation is used to reclaim metals including Cu purification and other metals, such as Pb, Cd, Bi *et al.* separation sequentially (**Fig. 4**) ([Wang and Xu, 2015](#)).

Glass or binder encapsulation, where harmful contents are safely sealed in, to produce low grade construction blocks, is a further emerging thermal process being developed at the expense of resources lost. Vacuum, thermal plasmas and lasers to enhance the thermal treatment are novel research topics being searched ([Kellner, 2009](#)).

Drawbacks of pyrometallurgical processes

Pyrometallurgical routes are generally more economical, eco-efficient and maximize the recovery of PMs, however, they have certain limitations that are summarized here ([Khaliq et al., 2014](#)):

- Recovery of plastics is not possible because plastics replace coke as a reducing agent and fuel as a source of energy;
- Fe and Al recoveries are low, due to the loss of noble metals into the slags, and are not easy as they end up in the slag phase as oxides;

Fig. 2 Boliden's Rönnskär smelter (Skelleftehamn, Sweden) flowsheet for Cu production. Reproduced from Zhang, L., Xu, Z., 2016. A review of current progress of recycling technologies for metals from waste electrical and electronic equipment. *Journal of Cleaner Production* 127, 19–36. doi:10.1016/j.jclepro.2016.04.004.

Fig. 3 Umicore Hoboken integrated smelter and refinery flowsheet.

- Hazardous emissions such as dioxins are generated during smelting of feed materials containing halogenated flame retardants. Therefore, special installations are required to minimize environmental pollution;
- A large investment is required for installing integrated e-waste recycling plants that maximize the recovery of valuable metals and also protect the environment by controlling hazardous gas emissions;

Fig. 4 Vacuum metallurgical separation of WPCBs.

- Instant burning of fine dust of organic materials (e.g., plastics) can occur before reaching the metal bath. In such cases, agglomeration may be required to effectively harness the energy content and also to minimize the health risk posed by fine dust particles;
- Ceramic components in feed material can increase the volume of slag generated in the blast furnaces, which thereby increases the risk of losing PMs from BMs;
- Partial recovery and purity of PMs are achieved by pyrometallurgical routes. Therefore, subsequent hydrometallurgical and electrochemical techniques are necessary to extract pure metals from BMs;
- Handling the process of smelting and refining is challenging due to complex feed materials. The expertise in process handling and the thermodynamics of possible reactions will be difficult.

Hydrometallurgical Metal Recovery Processes

The recycling of BMs and PMs is becoming more and more important, in order to counteract the depletion of scarce mineral resources, especially as the demand for these metals continues to increase. While all of the methods discussed above have proved effective at recovering metals from WPCBs, it is essential to develop more environmentally friendly processes that exhibit better performance in terms of both valuable-metal recycling and hazardous-substance control. These existing processes of recycling WPCBs focus on the recovery of the valuable materials in the WPCBs. Nowadays, physico-mechanical methods, which contain crushing, grinding, electrostatic separation, gravity separation, magnetic separation, density-based separation, etc., are widely employed to separate metals and nonmetals from WPCBs. Then, the nonmetal fraction (NMF) can be directly used as molding filler compound, concrete and modifier. After NMF modification high-value added products (i.e., catalysts, absorbents and filler support) can be produced. The recovered metallic powders may also need further purification before they can be utilized (Gao *et al.*, 2008). Zhu *et al.* (2013) separated WPCB bromine epoxy resin using dimethyl sulfoxide (DMSO) at S/L ratio of 1/7, 145°C for 60 min. Valuable metals and glass fibers are recovered after filtration and DMSO was regenerated.

For metals recycling from WPCBs without ECs, electrostatic separation (Hou *et al.*, 2010; Wu *et al.*, 2008; Li *et al.*, 2008; Li *et al.*, 2007), wet jigging (Sarvar *et al.*, 2015), froth flotation (Sarvar *et al.*, 2015; Estrada-Ruiz *et al.*, 2016), air current separation (Xue and Xu, 2013) etc., have been used to separate metals from nonmetals, pure metals can then be extracted from the mixed metals by vacuum metallurgy (Zhang and Xu, 2014; Zhan *et al.*, 2016; Zhan and Xu, 2011).

Hydrometallurgy (Chen *et al.*, 2015a; Jadhav and Hocheng, 2015; Chen *et al.*, 2015b; Qu and Li, 2014), biohydrometallurgy (Rodrigues *et al.*, 2015; Arshadi and Mousavi, 2015, 2014; Jadhav *et al.*, 2016; Chen *et al.*, 2015c) and supercritical fluid (Liu *et al.*, 2016; Calgaro *et al.*, 2015; Xiu *et al.*, 2015) have also been applied, to leach valuable metals from WPCBs. Valuable metals can be further recovered from leaching solution by adsorption-elution (Neto *et al.*, 2016) electrowinning (Fogarasi *et al.*, 2014, 2015) and so on. Nowadays, the main technologies used for the recovery of valuable metals from WEEE are based on pyrometallurgical and hydrometallurgical processes (Cui and Zhang, 2008). Generally, hydrometallurgical processes are technically more predictable and controllable in material extraction from resources (Cui and Zhang, 2008) and have already been applied in WEEE recycling for almost three decades (Zhang and Xu, 2016; Baba, 1987; Cui and Zhang, 2008; Sheng and Etsell, 2007; Behnamfard *et al.*, 2013). Thus, continued research on the recycling of WPCBs is necessary. Hydrometallurgical process is typically used to purify metallic powders, which are leached in aqueous solvents such as strong acids and alkalines. This is often applied together with other complexing agents, such as oxalic acid, acetic acid, cyanide, halide, thiourea, and thiosulfate. Hydrometallurgical process easily generates a large amount of

waste acid, alkaline liquid and sludge, which cause secondary pollution. Hydrometallurgical processes are less energy and cost demanding than pyrometallurgical treatments, and also applicable in plants with relatively small capacities (Le Ret and Briel, 2011). Biometallurgical technology, which based on microorganisms assisted reactions, has been regarded as a potential major technology breakthrough and has already applied in waste recycling. The leaching process is the initial and the most important step for both hydrometallurgical technology and biometallurgical technology. Pyrometallurgical processes require the heating of WEEE at high temperatures (often greater than 1000°C) to recover valuable metals. These thus represent highly energy-consuming treatments that lead to the production of hazardous gases that must be correctly removed from the air with flue gas cleaning/treatment systems. Recently hybrid technologies have also been applied, which integrate the chemical approach (more efficient) with biological strategies (more eco-compatible), thus taking advantage of the benefits of both chemical and biological leaching (Pant *et al.*, 2012).

Physico-Mechanical Separation Process

Physico-mechanical separation techniques include gravity, magnetic and electrostatic separators together. Simplified process flowsheet for a mixed WEEE metal recovery plant has a manual sorting line to remove batteries, toners/inks, paper and external cables; shredding and manual picking line/band to remove large capacitors, motors and transformers; over band magnetic separation to remove coarse ferrous metals; pulverizing followed by magnetic separation to remove again fine ferrous metals and steels; Eddy current separators (ECS) to separate metallic (Cu and Al) and nonmetallic (plastics, rubbers, glass, wood and stone) and finally Cu rich and Al rich materials can be separated by density separation (Kellner, 2009).

Gravity separation

Gravity separation is based on the specific density differences. Concentration criterion (CC) can be used for gravity separation using the following equation:

$$CC = (\rho_h - \rho_{\text{fluid}}) / (\rho_l - \rho_{\text{fluid}}) \quad (1)$$

where ρ_h : specific gravity of heavy material; ρ_l : specific gravity of light material and ρ_{fluid} : specific gravity of fluid medium (water/air). If $CC > \pm 2.5$, gravity separation is relatively easy until 74 μm . If $2.5 < CC < 1.25$, efficiency of gravity separation decreases. Separation is possible between 149 and 250 μm particle sizes. If $CC < 1.25$ gravity separation can be possible under careful density control conditions.

$$\text{For plastics and Al/glasses, } CC = (2.7 - 1) / (2 - 1) = 1.7 \quad (\text{Gravity separation is possible; but, not easy}) \quad (2)$$

$$\text{For plastics and metals, } CC = (7 - 1) / (2 - 1) = 6.0 \quad (\text{Gravity separation is easy}) \quad (3)$$

$$\text{For Al/glasses and metals, } CC = (7 - 1) / (2.7 - 1) = 3.53 \quad (\text{Gravity separation is easy}) \quad (4)$$

After required liberation, plastics and Al/glasses can easily be separated from metals by gravity separation methods. Plastics and Al/glasses gravity separation can be possible under careful specific gravity control conditions.

Gravity concentration methods separate materials of different specific gravity by their relative movement in water or air. Nonetheless, this separation is not only dependent on the density of the components, but also on their size and shape. Besides gravity one or more of the other forces, like force exerted by the viscous liquids, can serve as the separation medium (Kaya, 2016a). Rectangular riffled air tables can be used for e-waste sorting. By using different heavy liquids (such as tetrabromoethane-TBE (2.97 g cm^{-3}) and acetone, which lowers density and viscosity), the metals can be separated from the plastics or ceramics. Al metal went to the light fraction due to the lower density. Cu was more effectively separated at size 149 μm (Hanafi *et al.*, 2012). Water or airflow tables, heavy media separation and sifting are common gravity separators used in e-waste recycling. Different metal particles can be further separated. For this purpose, the WPCB material is processed on concentrating tables. The shaking tables exploit the difference in the specific gravity and particle size to achieve desired separation. The principle of the air classification technique is based on the suspension of the particles in a flowing air stream and the separation of the particles based on their density difference. Air tables move back and forward shaking at 200–300 rpm. Air tables have an upward tilt. They are equipped with a porous deck, which is inclined and subjected to vibration which causes material in contact with the deck surface to convey up the inclined surface of the deck. Low-pressure air by a blower is forced through the deck to fluidize the dry mixture so that the lighter materials are lifted from the deck surface and allowed to float down the inclination of the deck. The final result, presented at the discharge face of the deck, is a continuous, graduated progression from the least to most dense, smallest to largest, and least to most aerodynamic (Fig. 5). The feed side is lower and concentrate side is higher. Narrow size range feed (0.25–3.2 mm) is introduced to the air table (The riffles are always taller on the feed side of the table, and decrease in height as they progress towards the tailing side of the table). Material is fed perpendicular to the riffles and the high density material remains behind the riffles and low density material flows above and over the riffles. Air tables are used for separation of metallic and plastic components from a feed of $\sim 7 \text{ mm}$ in size after ferromagnetic separation. Recovery rates for Cu, Au and Ag of 76%, 83% and 91%, respectively achieved from low grade WPCB or general e-scrap. Gravity separation techniques which are well-known in the mineral processing industry have found their way into e-waste recycling based on the fact that e-scrap consists essentially of plastics, with a density less than 2.0 g cm^{-3} ; light metal, primarily Al and glass, with a density of 2.7 g cm^{-3} ; and heavy metals, predominantly Cu and ferromagnetics, with a density more than 7 g cm^{-3} . In sink-float separation, both PC and PCB scraps $\sim 50\%$ (weight) of floats which is primarily plastics can be separated out at the specific density of 2.0 g cm^{-3} (Zhang and Forssberg (1997)). Sarvar *et al.* (2015) used a jig for $+0.59$ and 1.68 mm WPCB particles.

Fig. 5 Gravity separator for e-waste recycling: (a) Dry shaking air table details, (b) schematic material separation, (c) air table working principles, and (d) industrial scale equipment.

Wet gravity separation

In the past, WPCB recycling lines with gravity separating type used widely wet gravity separators (i.e., hydraulic shaking tables, jigs, Falcon centrifugal separator etc.) to obtain only crude Cu metal particles from WPCBs. Metals and nonmetal (i.e., plastic and glass fiber) materials have different densities. If there is a large difference in densities, gravity separation is more economical than electrostatic separation. This process produces huge amount of waste water and residues, which may create serious secondary environmental problems. Other metals and nonmetals cannot be recycled (Huang *et al.*, 2009). Recently zigzag 3-way air classifiers were used for dry separation (pneumatic) to overcome above problems along with magnetic and electrostatic separators. Fig. 6 shows a typical wet gravity separation flowsheet for WPCB recycling. Cu metal can be separated from plastics. Ferrous material is removed after shredding by magnetic separators. Wet separation reduces air and noise pollutions, recycle water and reuse limited resources. Duan *et al.* (2009) used a Falcon SB40 centrifugal separator to recycle metals from WPCBs crushed to less than 1 mm. This separator separates materials by density using up to 300 g acceleration. Industrial scale plants have a capacity of 0.8–1.0 t d⁻¹, power requirement 160 kW, water requirement 20–30 t d⁻¹ and floor space requirement 150 m². Dimensions (l*W*h) are 26.3*6.1*6.4 m. Fe recovery rate is claimed to be 99% and Cu and epoxy resin recovery rates are more than 95% (Web 1). Angle of deck, length and frequency of stroke, splitter positions and riffle heights, feed rate and pulp density (above 40%) significantly affect the separation efficiency.

Dry gravity separation

Dry WPCB recycling equipment with air-separation type is applicable to recycle various waste and bare WPCBs. The mixture of metal and nonmetal materials gained from crushing-pulverizing-classifying of WPCB materials is fed into the material hopper of air separator, then into the separating zone of the separator to separate metal, glass fiber and resin mixtures. Since the separator is connected with a dust removal system, a horizontal air current is formed which moves the materials in horizontal direction. Meanwhile, with the action of the gravity, the materials move downward. Due to the different specific gravity of materials, nonmetal materials such as fine dust and grains with lower gravity are taken away by the dust removal system when the mixture passes the separating plate, leaving the metal materials with larger gravity into finished product recovery zone. Thus, the separation of metal from nonmetal materials is achieved. Zigzag (3-way) air classifiers remove the light part of heterogeneous materials by means of an air flow in counter-current inside a zigzag pipe. They clean residues and separate light parts in WPCB recycling. Fig. 7 shows zigzag air classifier details and dry gravity separation plant picture. Industrial scale plant capacity is about 0.2–0.3 t h⁻¹. Low noise, no need for water, no dust pollution, power and labor savings and no waste and above 95% metal and nonmetal recoveries are main advantages. Floor space requirement (l*w*h) is 7*5*5 m and load weight is more than 10 t. Dust pollution is prevented by two-in-one dust removal device: cyclone collector and pulse bag dust collector (Web 2). Air table techniques can be utilized for the separation of particulate fractions in the 5–10 mm, 2–5 mm and <2 mm ranges, respectively (Kellner, 2009). High

Fig. 7 Zigzag air classifier: (a) Working principle, (b) pilot plant classificatory, and (c) industrial scale equipment.

selectivity with high upgrading ratio and able to see separation and making adjustments, no need for addition thermal drying are advantages of dry air tables. Low capacity, large floor area requirements, frequent operator attention, checking and adjustment, noisy and dusty, dust control system requirement and feed sizing requirements are the main disadvantages.

Zhang *et al.* (2017) used vibrating gas-solid fluidized bed (VGFB) for recovering residual metals from nonmetallic fraction (Fig. 8). Vibrated fluidized bed column segregates metals, plastic organics and glass fibers at different size classes according to particle size, shape and density at different superficial air flow rates ($0.1\text{--}0.2\text{ m s}^{-1}$), fluidization frequencies ($20\text{--}30\text{ Hz}$) and fluidization times ($120\text{--}150\text{ s}$). Compared with coarse fraction, the segregation of fine particles has a need for lower vibration frequency and superficial air velocity but longer fluidizing time. The metal recoveries of $-1 + 0.5\text{ mm}$, $-0.5 + 0.25\text{ mm}$ and -0.25 mm size fraction are 86.4%, 82.2% and 76.6% respectively, meaning the bad segregation efficiency of VGFB for fine particles.

Reproduced from Zhang, G., He, Y., Wang, T., *et al.*, 2017. New technology for recovering residual metals from nonmetallic fractions of waste printed circuit boards. *Waste Management* 64, 228–235. doi:10.1016/j.wasman.2017.03.030.

Dry air tables use a shaking motion similar to that of wet shaking tables, but instead of water, air is used to separate heavy materials. The table deck is covered with porous material and air is blown up through the deck from a chamber underneath. The chamber equalizes the pressure from the compressor and thus ensures an even flow of air over the entire deck surface. Generally, air tables consist of a ripped top deck mounted over a base that contains a compressor. The deck is tilttable and riffles are tapered, much like a wet shaking table. The attached motor powers the system. The dry feed is introduced at one corner of the deck. The deck is shaken laterally and air pressure is regulated to keep lighter materials move down slope along the shortest route. Heavier particles move upslope due to the movement of table. Splitters allow and adjustable middling fraction to be collected (Web 3).

Electrostatic separation

Electrostatic separation (E-sorting) adopts high voltage electrostatic processing principle, separating the conductive metal and nonconductive nonmetal/nonferrous materials according to their conductivity/resistivity differences. Conductors have valence electrons from a sea of electrons between positive ion cores and insulators have valence electrons tightly bounded to nucleus. Ag, Cu, Au, Fe, Al, Mg, Zn, Cd, Ni, Sn, graphite are conductor and ceramic, glass, plexiglas, wood, paper, plastic, teflon, paraffin and resin are nonconductor (insulator/dielectric) components of WPCBs. Conductors have high conductivity and nonconductors do not have conductivity. Electrostatic separation system is the most innovative technology for an efficient final stream granulometric separation in recycling processes. Exploiting the electric fields generated the more conductive fraction (i.e., metallic) can be separated from the lower conductive fraction (for instance paper, plastic, rubber) (Web 4). The charged nonconductors are attracted to an oppositely charged electrode and collected.

A conductive material allows electrons to flow easily across its surface or through its volume. When a conductive material becomes charged, the charge (i.e., the deficiency or excess of electrons) will be uniformly distributed across the surface of the material. If the charged conductive material makes contact with another conductive material, the electrons will transfer between the materials quite easily. If the second conductor is attached to an earth grounding point, the electrons will flow to ground and the excess charge on the conductor will be “neutralized”. A material that prevents or limits the flow of electrons across its surface or through its volume is called an insulator. Insulators have an extremely high electrical resistance. A considerable amount of charge can be generated on the surface of an insulator. Because an insulative material does not readily allow the flow of electrons, both positive and negative charges can reside on insulative surface at the same time, although at different locations. The excess electrons at the negatively charged spot might be sufficient to satisfy the absence of electrons at the positively charged spot. However, electrons cannot easily flow across the insulative material's surface, and both charges may remain in place for a very long time.

The particles may be charged through contact electrification, conductive induction or high tension (ion bombardment). However, triboelectric charging is the most common. High voltage ionization, induction, tribo charger and lifting electrodes can be used around rotating grounded drum. One or more than one electrode series can be employed for charging. Conductor materials are pulled towards positive charging electrode(s). Nonconductors are scraped from the surface of rotating drum with brushes. There are three typical electrical conductivity-based separation techniques: (1) Corona electrostatic separation (CES), (2) Triboelectric separation (TES) and (3) Eddy current separation (ECS) (Kaya, 2016b). The electrostatic separating capability depends on the difference in polarity and the amount of charge acquired by particles to be separated. Induction or Corona charging can successfully separate the mixed particles that have large difference in conductivities. Tribo-electricity or contact charging is useful for charging and separating materials that have similar conductivities. The principle of ECS is that in separation zone gravitational, centrifugal, frictional, and magnetic deflection forces influence the falling particles, but only magnetic force deflects the ferrous particles to a higher degree. To separate ferrous particles, the magnetic deflection force acting on the ferrous

Fig. 9 CES separator: (a) Principle of separation operation, and (b) laboratory scale equipment.

particles has to be greater than all competing forces (Li *et al.*, 2004). Some examples of the use of high voltage electrostatic separators: metal-plastic separators ($8.0 \text{ mm} > d_p > 0.1 \text{ mm}$) and plastic-plastic separators ($2 < d_p < 12 \text{ mm}$) (Web5). They are used for:

- Dry separation (ideal surface moisture $< 0.2 \%$) of light fractions of metals (Cu and Al) from the nonconductor plastic fraction of the recycling operations of cables and electrical wiring at $8.0 \text{ mm} > d_p > 0.1 \text{ mm}$ in size.
- Recovery of light fractions PMs (Au, Ag and Pd) in the recycling of WPCBs, e-scrap and WEEE at $8.0 \text{ mm} > d_p > 0.1 \text{ mm}$ in size.

Corona electrostatic separation

The rotor type Corona-electrostatic separation (CES) method is perhaps the most effective separation technology for the conductive (metallic) and nonconductive (nonmetallic) fractions at present. The method has the advantage of being environmentally friendly, producing no wastewater and no gaseous emissions. In the CES, electrode system, rotor speed, moisture content and particle size have the greatest effect in determining the separation results. CES can be used for recovery of Cu or Al from chopped electrical wires and cables and for the e-sorting, downstream of the WPCB system, separates metals and allows to recover the finer fractions of PMs. The WPCBs with the metallic components removed must be reduced to very small particles, which can be achieved by accelerating them at high speed to impact on a hardened plate. Then, the small particles, typically less than 0.6 mm are passed along a vibratory feeder to a rotating roll to which is applied a high voltage electrostatic field using a Corona and an electrostatic electrode (Lu *et al.*, 2008; Hadi *et al.*, 2015). The nonmetallic particles that become charged and attach to the drum eventually falling off into storage bins; whereas the metallic particles discharge rapidly in the direction of an earthed electrode. Fig. 9 shows the principles of separation operation and laboratory scale CES equipment.

There are two series of CES machines: double-rollers and multi-rollers electrostatic separators. Roller length changes from 1000 to 2000 mm , roller quantity $1-4$, power $1.5-4 \text{ KW}$, speed $20-300 \text{ rpm}$ and outlet motor $0.75-2.2 \text{ kW}$ at a production capacity between 300 and 500 kg h^{-1} . Separation efficiency is as high as 99% . Electrostatic separator features a high precision separation with easy operation and simple maintenance. They cover a small area and easily move. It has been found that particle sizes of $0.6-1.2 \text{ mm}$ are the most suitable size for separation in industrial applications. Therefore, a two-step crushing process (shredder + hammer mill) has been proposed to achieve this particle size. Li *et al.* (2008) found that as the angle of the static electrode reduced and the Corona electrode angle was increased, the separation efficiency was enhanced. It was reported that applied voltage of $20-30 \text{ kV}$, center distance of 21 cm , static electrode radius of 1.9 cm , Corona wire radius of 11.4 cm , static electrode angle of 20° and Corona electrode angle of 60° were the optimum operating parameters influencing the separation efficiency. Considerable work is continuing in this area with particular focus on the electrostatic behavior of the system and the field intensity (Hadi *et al.*, 2015). CES methods are now capable of producing two streams from WPCB comprising a metallic and a nonmetallic portion with little cross-contamination; the method is dry at room temperature and as such is almost zero polluting depending on the quality of the dust extraction system. The residual Cu metal in nonmetallic fraction, which were separated from WPCBs without ECs by using the CES, showed that most of the residual Cu is in fine size range ($7-9 \mu\text{m}$) (Gao *et al.*, 2008).

Industrial scale electrostatic separators (Fig. 10) adopt physical high voltage to separate conductor metals from nonconductor nonmetals with a separation efficiency of $95\%-99\%$ purity. Electrostatic separator power changes from 1.5 to 3 kW , rotational speed from 20 to 300 rpm , static electricity from $50,000$ to $150,000 \text{ volt}$ adjustable (Web 6). Considerable work is continuing in this area with particular focus on the electrostatic behavior of the system and the field intensity.

Triboelectric separators

Static electricity is defined as an electrical charge caused by an imbalance of electrons on the surface of a material. Electrostatic charge is most commonly created by the contact and separation of two similar or dissimilar materials. Creating electrostatic charge by contact and separation of materials is known as “triboelectric charging”. It involves the transfer of electrons between materials. The atoms of a material with no static charge have an equal number of positive protons in their nucleus and negative electrons orbiting the nucleus. The amount of charge created by triboelectric charging is affected by the area of contact, the speed of separation, relative humidity, and other factors. Once the charge is created on a material, it becomes an “electrostatic” charge. This charge may be transferred from the material, creating an electrostatic discharge event. When the two materials are placed in contact and then separated, negatively charged electrons are transferred from the surface of one material to the surface of the other material. Which material loses electrons and which gains electrons will depend on the nature of the two materials. The material that loses electrons becomes positively charged, while the material that gains electrons is negatively charged.

This imbalance of electrons produces an electric field that can be measured and that can influence other objects at a distance. Electrostatic discharge is defined as the transfer of charge between bodies at different electrical potentials. When two materials contact and separate, the polarity and magnitude of the charge are indicated by the materials’ positions in the triboelectric series. The triboelectric simply lists materials according to their relative triboelectric charging characteristics. When two materials contact and separate, the one nearer the top of the series takes on a positive charge, the other a negative charge. Materials further apart on the table typically generate a higher charge than ones closer together. Triboelectric charging properties of materials found in WPCBs can be seen in [Table 2](#). Some substances have positive and some have negative charging characters. [Fig. 11](#) shows the industrial scale TESs along with separation equipment.

Eddy current separators

An Eddy current separator (ECS) uses a powerful magnetic field to separate nonferrous metals from waste after all ferrous metals have been removed previously by some arrangement of magnets. The device makes use of eddy currents to effect separation. ECSs are not designed to sort ferrous materials, which become hot inside the eddy current field. This can lead to damage of ECS unit belt. ECS is applied to a conveyor belt carrying a thin layer of e-waste. Nonferrous metals are thrown forward from the belt into a product bin, while nonmetals simply fall off the belt due to gravity. ECSs use a rotating drum with permanent/electro magnet. [Fig. 12](#) shows the separation principles of ECS and pilot-scale equipment. It is mainly used for recycling Cu, Al and other nonferrous metals from industrial waste and living garbage waste, can be widely used in garbage disposal, recycling of WEEE, other environmental industry and nonferrous metal materials processing industry. The main criterion to distinguish is the ratio of material conductivity and density values, the higher ratio value is more likely to separate. Typical particulate sizes processed tend to be in the 3–150 mm size range. High frequency ECSs, where the magnetic field changes very rapidly, are needed for separation of smaller particles ([Kellner, 2009](#)).

ECSs produce high frequency alternating magnetic field on magnetic roller; if conductive nonferrous metal goes through the magnetic field, it will produce induced current and this induced current will produce magnetic field opposite with original magnetic field, then the nonferrous (i.e., Al, Cu etc.) metal will fly ahead according its transporting direction by repulsive force of the magnetic field; hence, nonferrous metal is separated from other non-metal material. ECSs are composed of a separator and an electric controlling cabinet. Main body includes separating assembly, motor, frame and cover etc. Separating assembly includes permanent magnet roller (FeBNd), transporting system (includes transporting belt, driving roller and reducer). ECSs have a good separating result for multiple nonferrous metals, strong adaptability, reliable structure, strong adjustable repulsion with high separating efficiency. Magnet roller diameter is generally 300 mm. Magnet roller revolution changes up to 3000 rpm. Belt

Highest capacity plants have one double-shaft shredder, hammer mill, bucket elevator and storage bin; two belt conveyor, specialized crusher, classifier, cyclone, four level cyclone, three-in-one dust catcher, vibrating screen; four electrostatic separator and six bucket elevators. **Fig. 13** shows industrial scale integrated physico-mechanical WPCB recycling plant flowsheet with air separator and ECSs along with feed-product photos obtained.

Magnetic separation

By creating an environment comprising a magnetic force (F_m), a gravitational force (F_g) (determined by particle size and density) and a drag force (F_d) (for wet magnetic separators determined by particle diameter, shape, liquid viscosity and velocity and for dry magnetic separators, determined by particle size, density and air velocity) magnetic particles can be separated from nonmagnetic particles by magnetic separation. Magnetic separators (MS) exploit the difference in magnetic properties between particles. All materials are affected in some way when placed in a magnetic field.

$$\text{Magnetic attraction force (F}_m\text{)} = V * X * H * \text{grad}H \quad (5)$$

Where V: Particle volume (determined by process)

X: Magnetic susceptibility

H: Magnetic field (created by the magnet system design) in mT

Grad H: Magnetic field gradient (created by the magnet system design) in mT

(mT: milli Tesla, 1kGauss = 100 mT = 0.1 T, 1 T = 10,000 Gauss)

Materials are classified into two broad groups according to whether they are attracted or repelled by a magnet. Non/diamagnetics are repelled from, and ferromagnetics/paramagnetics are attracted to a magnet. Ferromagnetic substances are strongly magnetic and have a large and positive magnetism. The magnetic moments in ferromagnetic material are ordered and of the same magnitude in the absence of an applied magnetic field. Paramagnetic substances are weakly magnetic and have a small and positive magnetism. The magnetic moments in a paramagnetic material are disordered in the absence of an applied magnetic field and ordered in the presence of an applied magnetic field. In diamagnetic materials, magnetic field is opposite to the applied field. Magnetisms are small and negative. Nonmagnetic material has zero magnetism. These materials are not attracted towards magnet.

Ferromagnetism is the basic mechanism by which certain materials (such as Fe) form permanent magnets, or is attracted to magnets. Ferromagnetism (including ferrimagnetism) is the strongest type. Ferromagnetic materials can be separated by Low Intensity Magnetic Separator (LIMS) at lower than 2 T magnetic intensity. Paramagnetic materials can be separated by dry or wet High Intensity Magnetic Separators (HIMS) at 10–20 T magnetic intensities. Diamagnetic materials create an induced magnetic field in a direction opposite to an externally applied magnetic field, and are repelled by the applied magnetic field. Non-magnetic substances have little reaction to magnetic fields and show net zero magnetic moment due to random alignment of magnetic field of individual atoms. Strongly magnetic materials can be recovered by a magnetic separator with the use of relatively weak magnetic

induction, up to 0.15 T. Weakly magnetic materials can be recovered by a HIMS generating induction up to 0.8 T with modest values of the gradient of the magnetic field. Induced roll separators, field intensities up to 2.2 T and Permroll separators can be used for coarse and dry materials ($> 75 \mu\text{m}$). Fine materials reduce the separation efficiency due to particle-rotor and particle-particle adhesion/agglomeration. For wet HIMS, Gill and Jones separators are used at a maximum field of 1.4 and 1.5 T, respectively at $-150 \mu\text{m}$ size (Wills, 1988).

Dry LIMs are used for coarse and strongly magnetic substances. Magnetic field gradient in separation zone (approximately 5 cm from drum surface) changes 0.1–0.3 T. Below 0.5 cm, dry separation tends to be replaced by wet methods (wet LIMS). Concurrent and countercurrent drum separators have nonmagnetic drum containing three to six stationary magnets of alternating polarity. Separation depends on pick up principles. Magnetic particles are lifted by magnets and pinned to the drum and are conveyed out of the field. Field intensities up to 0.7 T at the pole surfaces can be used. Coarse particles up to 0.5–6 mm can be tolerated. Drum diameter is 1200 mm and length 600, 1200, 1800, 2400, 3000 and 3600 mm. Concurrent operation is normally used as primary separation (cobber) for large capacities and coarse feeds. Countercurrent operation used as rougher and cleaner for multistage concentration.

Moderately magnetic dry substances on a conveyor/belt can be collected by overhead, cross-belt or disc separators using magnetic field intensities between 0.8 and 1.5 T. Very weakly paramagnetic substances can only be removed if field intensities are greater than 2.0 T. At 5–200 mm size fraction, overhead permanent magnets are used to remove ferromagnetics. Magnetic separators, such as dry low-intensity drum types, are widely used for the recovery of ferromagnetic materials from nonferrous metals (Al and Cu) and other nonmagnetic materials (plastic and glass) at -5 mm in size. The magnetic field may be generated by permanent magnets or electromagnets. There have been many advances in the design and operation of HIMS due mainly to the introduction of rare-earth alloy permanent magnets with the capability of providing high field strengths and gradients. There are some problems associated with this method. One of the major issues is the agglomeration of the particles which results in the attraction of some nonferrous fraction attached to the ferrous fraction (Veit *et al.*, 2005). This will lead to the low efficiency of this method. Through the process of magnetic separation, it is possible to obtain two fractions: Magnetic fraction, which includes Fe, steel, Ni etc. and nonmagnetic fraction, which includes Cu (Yamane *et al.*, 2011). For WEEE, magnetic separation systems utilize ferrite, rear-earth or electromagnets, with high-intensity electromagnet systems being used extensively.

Veit *et al.* (2005) employed a magnetic field of 0.6–0.65 T to separate the ferromagnetic elements, such as Fe and Ni. The chemical concentration of the magnetic fraction was 43% Fe and 15.2% Ni on average. However, there was a considerable amount of Cu impurity in the magnetic fraction as well. Yoo *et al.* (2009) used a two-stage magnetic separation to milled WPCBs. The milled WPCBs of particle size $> 5.0 \text{ mm}$ and the heavy fraction separated from the $< 5.0 \text{ mm}$ WPCBs particles by gravity separation. In the first stage, a low magnetic field of 0.07 T was applied which led to the separation of 83% of Ni and Fe in the magnetic fraction and 92% of Cu in the nonmagnetic fraction. The second magnetic separation stage was conducted at 0.3 T which resulted in a reduction in the grade of the Ni–Fe concentrate and an increase in the Cu concentrate grade. Hanafi *et al.* (2012) had an agglomeration problem of nonmetals which were pulled with ferrous materials.

Conclusions

Conventional processes for WPCB recovery include incineration/combustion, mechanical separation with gravity separation methods and crude acid leaching. Incineration is a traditional process and accepts every e-waste as its (i.e., mixed and without size reduction). Process time is short and heat energy is produced. Incineration is irreversible process and changes the chemical and physical phases very high. Process capacity is large, and product efficiency, recovery rate and purity are low. Selectivity between metals is low. Incineration is environmentally unfriendly and requires expensive gas purification systems. Equipment used should resist to corrosion. From the incineration process, only Cu, Au and Ag metals are recovered from the ashes, and Fe and Al cannot be recovered. WPCBs, which include plastics and some reusable ECs, are burned and lost. Cu can be purified by H_2SO_4 leaching. Au and Ag can be recovered from the Cu electrolysis mud.

Mechanical separation includes size reduction and gravity separation processes. Multi-step crushing/shredding and pulverizing/grinding only liberates low value plastics from metals. Metals are not liberated from each other. Two-step size reduction is generally preferred. Size reduction generates excess heat, toxic gases, noise and dust. There is a significant PM loss in dry separation due to liberation problem. Dry separators must require dust removal system. Wet gravity separation can reduce dust and noise problems; but, it generates waste water matter. Air tables and zigzag 3 way classifiers do not have waste water problem. Wet shaking tables, heavy media separation and jigs produce huge waste water. Recovery rate in gravity separation is as high as 95%. Gravity separation is more economical than electrostatic separation in metal and plastic/Al/glass segregation.

Advanced pyrometallurgical process for WPCB recovery is currently most commonly used process in the industry. Integrated smelters and refineries accept both WPCBs directly without size reduction to reduce PM losses and raw ores. Removing massive Fe and Al parts for valorization and upgrading Cu and PMs is required. Process time is short in pyrometallurgical treatment. However, smelting is energy intensive ($> 1200^\circ\text{C}$) process. Initial investment and energy costs are very high. Plant capacity is large. Product efficiency, recovery, selectivity and purity are low as compared to hydrometallurgical processes. Pyrometallurgical processes are environmentally unfriendly, require expensive gas purification systems for VOCs, dioxins and furans and necessitate corrosion resistant equipment. From an ISR plant, 20 different metals can be recovered along with hydrometallurgical and electro-metallurgical techniques. Glass and plastics are lost and converted to slag, ash and heat energy.

Hydrometallurgical processes are advanced and promising aqueous recovery techniques for metals from WPCBs. They are easy to apply, simple to operate and selective, flexible and stable to use. Higher recovery rates, faster kinetics, easier control, lower temperature requirement, less hazard to environment, low gas emission, low energy consumption, low initial investment cost, higher recovery rates and more predictable results are some of advantages of hydrometallurgy as compared to pyrometallurgy. Reagent recyclability and selective recovery of both all BMs and PMs are important benefits of the hydrometallurgical processes. However, the use of strong and corrosive reagents, long process time, discharged toxic wastes and high cost of recovery are some of the disadvantages of hydrometallurgical process.

Currently, pyrometallurgical WPCB recycling routes are generally used globally (about 70%) with high investment cost, temperature and ecological problems. Smelting process segregates and upgrades PMs into BMs followed by hydrometallurgical and electrometallurgical processing for the recovery of pure BMs and PMs. Comparing with the pyrometallurgical processing, hydrometallurgical method is better, more predictable, and more easily controlled. New promising biological processes are now under development.

Metals and nonmetals/nonferrous materials in WPCB can be dry separated by electrostatic separation. There is no water requirement and no gaseous emission from this process. Environmental friendly electrostatic separation is performed at room temperature with a separation efficiency 95%–99% purity. Dust extraction requirement is only disadvantage of the process. CES separates Cu from plastics and mixed particles that have similar conductivities at a separation efficiency as high as 99% for particle sizes between 0.6 and 1.2 mm. Easy operation, simple maintenance, small area requirement and little cross contamination are some important advantages of this separation process. TES separates two similar or dissimilar materials by contact charging. ECS separates nonferrous metals of Al and Cu from plastics at a particle sizes at 3–150 mm.

Magnetic separators separate magnetic particles from nonmagnetic WPCB particles in dry or wet medium. In dry separation, there is an agglomeration problem. LIMS separates ferromagnetic fraction from Cu, Al and plastics at lower than 2 T magnetic intensity. Dry LIMS are used for coarse particles (0.5–6 mm) and wet LIMS are used for fine particles (< 0.5 mm). HIMS separates paramagnetic materials at 10–20 T magnetic intensity.

Second generation physico-mechanical separation (Gravity + Magnetic + Electrostatic) along with hydrometallurgical treatment approaches offers a cost effective, eco-friendly and more sustainable alternative methodology to smelting. Physico-mechanical WPCB recycling is a promising recovery technology without environmental pollution and with reasonable equipment invests, low energy cost and diversified potential applications of products. However, separation between the metallic and non-metallic fraction from WPCBs has to be enhanced. In the future, author believes that unlocking the hidden value from waste electronic asset/e-waste by Urban Mining will gain more importance in the World.

PREFACE

The *Encyclopedia of Renewable and Sustainable Materials* is a novel initiative, launched to cater for researchers, industrial practitioners and environmental conservationists to bring to the fore the issues of renewability, regeneration, recyclability and sustainability of natural material resources for the greater good of the environment, society and renewable resources. With these objectives the project was constituted of 11 sections, led by one Section Editor each. There are about 4,000 printed pages, accommodated in five volumes ranging from 600 to 1000 pages each.

This encyclopedia is the primary reference source for researchers at different levels and stages in their career in academia and industry and those with an interest in environmental protection and sustainability, including re-use and recycling of natural and synthetic materials and regeneration of natural materials. The work encompasses the knowledge and understanding of many experts into a single, comprehensive work of about 370 articles comprising a combination of review articles, case studies and research findings resulting from research and development activities in both industrial and academic domains. The encyclopedia, focuses on how some of these topics bring advantages for a broad range of technologies and environmental protectionists. These include harnessing existing materials both natural and synthetic, their re-usability and regeneration possibilities for the greater good of society and the environment. The aspects of feasibility, conservational objectives and practicability of implementation have been addressed through a number of relevant articles.

As Editors in Chief of this five-volume comprehensive publication, a truly collaborative work, we are greatly indebted to the 11 Section Editors who are internationally renowned experts in their fields, for guiding and selecting the topics for their respective sections which constitute the five volumes, commissioning authors and reviewing the contents so meticulously. Their true dedication to the scientific community and society is reflected in the time and energy they have given to this project. My sincerest thanks are due to all the authors – researchers, environmental protectionists and practitioners who have contributed extensive coverage of literature review as well as recent works of research to this substantial five volume encyclopedia. The excellent insight and specialist knowledge in their respective fields is reflected in the high quality content of this unique work.

Both of us and all the section editors are greatly appreciative of all the hard work undertaken by all concerned to turn this concept of the *Encyclopedia of Renewable and Sustainable Materials* into a publishable work. Our special thanks go to Ruth Rhodes and Michael Nicholls, the Project Manager, along with Kshitija Iyer and the rest of the team at Elsevier who served successively to keep the project on track through friendly nudges in order to ensure timely completion. We are also hugely grateful to other colleagues at Elsevier production unit for the coordination of the proofs.

The extensive research treatment of core ethos of renewability, recyclability and regeneration, supplemented by applied case studies has drawn together many areas of research and we sincerely hope that this work will prove to be of great help to both the young and experienced members of the international research community, academics and industrial practitioners associated with sensible utilization of natural and synthetic materials for many years to come.

Saleem Hashmi and Imtiaz Ahmed Choudhury
Editors in Chief – *Encyclopedia of Renewable and Sustainable Materials*

Critical Raw Materials (CRM) Recovery – Significance and Impact on Circular Economy

In the present world, raw materials are in greater demand but are becoming ever scarcer. To imply the sign of criticality, knowing that there is a high risk of supply shortage and economic impact, the European Commission formally adopted a list of specific raw materials designated as ‘critical raw materials’ (CRMs) as represented in Fig. 1. Regulatory policies are being implemented to bring down the extraction/mining trend for ultimately extending the lifetime of CRMs. On the other hand, advanced recycling systems are being practiced to promote and establish a core circular economy context by recycling, recovering, and separating CRMs. These recycling approaches are mostly aimed at the recovery of various metals such as palladium, gallium, germanium, copper, which are critical raw materials for the technology sector. There are also a specific group of CRMs including Phosphorus (P), natural phosphate rock and Magnesium (Mg) representing major primary, and secondary resources for industrial applications of high economic value (Loganathan *et al.*, 2017; Yan *et al.*, 2018). Crucially only P and Mg are deemed suitable candidate CRM’s for

Fig. 1 List of CRMs (shaded blue) among which phosphorus, phosphate rock and magnesium are highlighted for its representation in greater scale of economic importance and supply risk. Courtesy: Study of the review of the list of Critical Raw Materials, 2017.

recovery from waste streams through effective separation and recycling strategies. Further, its supply-demand status and substitutability risks have driven the requisites for resource supplementing technology through effective recovery and recycling strategies.

The core focus of this article is to review the most effective sustainable technologies to recover CRMs. Specifically for P and Mg recovery, it is essential to balance the depletion of its primary reserves, whilst mitigating the disposal issues with a view to remediate industrial brine/waste sludge rich in Mg and P nutrients respectively. Hence, special emphasis has been given to recovering CRMs from waste streams, currently a source of both high potential and environmental, and health concerns. Long-time benefits would be possible by the recovery of P and Mg as a secondary resource to ameliorate the CRMs supply risk in countries deprived of natural mineral reserve. Perhaps, natural lifecycle of phosphate could be balanced by maintaining its sustainable supply to plants while controlling eutrophication, a phenomenon leading to excessive oxygen depletion in water bodies owing to disproportionate phosphate discharge. In a viewpoint to achieve dual advantage of discharging pollutant-free waste sludge and to allow efficient recovery of P/Mg in different forms useful to mankind and environment, robust recycling/recovery strategies are consolidated and discussed in the following sections.

Overview on Conventional Approaches of P and Mg Recovery

As the levels of CRMs in the natural sources are limited, their recovery from non-conventional secondary sources such as end-of-life products and waste generated through industrial activities is essential to meet the global demand. Various conventional methodologies are reported in literature based on physical, chemical and biotechnological principle for the critical raw material recovery for magnesium and phosphorus. General summary on the widely adopted spectrum of methodologies for the P and Mg recovery are discussed in this section.

Since P is an essential component of fertilizer composition, the waste water produced from fertilizer industry is considered as an important secondary source for the recovery of P. Other sources utilised for P recovery include effluent from waste water treatment plants, household activities, municipal waste and industrial organic solid waste. While sea water is considered as a largest source of Mg, exhausted waste brine solutions from industry is also Mg rich.

The widely used methodologies for the recovery of divalent Mg and P mainly involve chemical precipitation, adsorption and membrane separation. Chemical precipitation is considered as a most popular method which involves leaching of Ca/Mg using acidic or alkaline conditions followed by their precipitation by adding metal hydroxide such as calcium hydroxide. The precipitation of P is achieved in the form of struvite (magnesium ammonium salt) and hydroxyapatite. Further, manipulation of Ca/P ratio and calcium phosphate concentration in solution, leads to fast precipitation and recrystallization of phosphate (Vasenko and Qu, 2018). In addition a hybrid methodology involving both oxidation and ultra-sonication assisted pre-treatment, was found to improve P recovery. In recent reports, electrolytic system in combination with ion-exchange membrane was demonstrated where OH^- ions released from water breakdown help in the precipitation of Mg (Sano *et al.*, 2018).

Adsorption methodology is considered a relatively simple process for the recovery of metal ions from aqueous waste. Activated charcoal and metal oxides such as ferric oxide/hydroxide, activated aluminium oxide and lanthanum oxide are well explored for their ability to adsorb metals from aqueous solutions. Ion-exchange resins are also used for metal ion recovery. The use of Anion exchange resin and cation exchange resins was studied for the recovery of P and Mg respectively. Further, application of magnetic ion-exchange (MIEx) resin is demonstrated for the recovery of Mg and P (Kim, 2015; Lehmann *et al.*, 2014). MIEx are adsorptive resins where iron oxide particles, with magnetic properties, are incorporated into a polymeric matrix. MIEx assisted adsorption can be combined with membrane separation, and precipitation methods, to improve the recovery of metal ions. Recently Lanthanum based nanoparticles and nano-composites receiving greater attention for the recovery of Phosphate from aqueous solutions (Wu *et al.*, 2017). Membrane separation is another popular method for the concentration and recovery of metal ions. Microfiltration, ultra-filtration, nanofiltration and dia-filtration have largely been demonstrated for the recovery P and Mg. Further, membrane separation is used in combination with ion-exchange resin and precipitation methodologies to improve the process recovery.

Advanced Technologies for CRM Recovery

Status of Phosphorus

Stimulated by the fact that phosphate rock resources have started depleting, the P recovery from any phosphorus-rich residue has drawn extensive attention to meet the industrial demand for P. The elevated phosphate concentration in wastewater/waste sludge presents significant opportunities for P recovery techniques to be readily integrated into current wastewater treatment infrastructure. Phosphate rock is the major natural source of phosphates used in fertilisers but the P extraction rate far exceeds the regeneration, thus estimating its depletion in the next 40–100 years. In contrast, 90% of the phosphate in wastewater is trapped in the sludge solids and also present as soluble PO_4 in the reject wastewater (> 80% of total P) (Yan *et al.*, 2018). Fig. 2 illustrates the simplified scheme of natural P cycle and its flows and distributions in global food chain. However the challenge remains to directly recover P/ PO_4 from municipal wastewater which redirects the focus to recover P as secondary resources for its significance in various industrial applications (Fig. 3).

Fig. 2 Scheme illustrating the potential of P recovery in partial closing the loop of global P cycle. Re-drawn with permission from Venkiteshwaran, K., McNamara, P.J., Mayer, B.K., 2018. Meta-analysis of non-reactive phosphorus in water, wastewater, and sludge, and strategies to convert it for enhanced phosphorus removal and recovery. *Science of the Total Environment* 644, 661–674.

Fig. 3 P and Mg based secondary raw materials its broad applications.

Struvite is one of the widely attracted secondary raw material rich in both P and Mg. It is interesting to note that resources constituting Mg is crucial to maximize the P separation based on either conventional precipitation or novel osmotic membrane separation methods. Calcium phosphate is yet another promising P based raw material, allowing recovery directly from the liquid phase (as dissolved P), which is not otherwise possible using conventional biological based wastewater treatment. If P can be

Table 1 Classification of membrane processes specific to desired mineral recovery

<i>Mg/P based raw materials</i>	<i>Hybrid membrane processes</i>	<i>Sources</i>
CaPO ₄	Nanofiltration-Crystallization Nanofiltration-Membrane Crystallization Microfiltration-Osmotic Membrane Bioreactor-Reverse osmosis	Secondary effluent Activated sludge Municipal wastewater Anaerobic digested sludge Wastewater
P, Mg	Electrodialysis Electrodialysis-Anaerobic Bioreactor	
MgSO ₄	Membrane distillation-crystallization	NF/RO retentate (real time/ simulated)
Struvite	Selectrodialysis-struvite bioreactor Membrane Crystallization	Anaerobic sludge Municipal wastewater
PO ₄	Microfiltration-Forward osmosis membrane bioreactor Electrodialysis-Membrane Bioreactor	Municipal wastewater Phosphorus rich wastewater
MgPO ₄	Combined membrane gas separation	Swine manures
PO ₄ , MgCl ₂	Osmotic Membrane Bioreactor-Membrane distillation	Activated sludge

removed and recovered at the very beginning of the wastewater treatment, then steps related to downstream processing of P-rich sludge could be avoided.

Status of Magnesium

The economic gains obtained by extracting minerals depend mainly on the concentration of minerals and their market price. In this respect, Na, Ca, Mg, K, Li, Sr, Br, B and U are potentially attractive for extraction, provided economically feasible extraction methods can be found to avoid direct land mining. There is a great demand for the group of minerals that can be profitably extracted from seawater, or effluent brine to benefit agriculture, industry, environmental remediation, and medicine. Mg is identified to be one of the key CRMs posing a huge demand, owing to its application in wide spectrum of industries including chemicals, construction materials, aluminium, steel and fertilizers. With magnesite being a prime source for Mg recovery, the growing demand and faster depletion of naturally occurring mines has led to the exploration of other Mg sources including dolomite, forsterite and brucite deposits. Mg and P are rather different class of CRMs that does not fall into the categories of precious metals like gold, silver and palladium; and selected set of critical metals (S-CRMs) like gallium, indium, rare earth elements (REEs), tantalum, and cobalt. Moreover, such different classes of CRMs, except Mg and P, could be readily recovered by recycling the WEEs. The world production of Mg is around 12 million ton per year (2012), but only 14% is produced in EU area. If the Mg recovery from waste brine of European saltworks are highly efficient, then the production from the EU zone could increase by 5% (Nakoa *et al.*, 2016).

Membrane Based Approaches for P and Mg Recovery

Combining P recovery with domestic/industrial wastewater treatment systems

To overcome the limitations related to lower P recovery and high cost required (e.g., the addition of inorganic salts like Mg) for conventional precipitation, it is rather important to focus on advanced separation technologies like membrane processes for improving the P recovery. Research interests on P recovery using forward osmosis, selective electrodialysis, and osmotic membrane bioreactor as an integrated process have recently been increased (Qiu *et al.*, 2016). Table 1 summarizes some of the feasible combination of membrane processes for recovery of P and Mg based raw materials from different waste resources. Thermally driven membrane processes like membrane distillation (MD) and membrane crystallization (MCR) have been widely used for desalination with simultaneous recovery of MgSO₄·7H₂O, owing to its well-controlled and easy tuneable precipitation at low energy requirements, which are difficult to obtain from normal crystallization processes. However, MCR/MD for P recovery is also feasible to produce both solid struvite precipitate, and ammonia rich liquid stream, while also being operated using waste heat to ensure a lean cost process.

In most of the osmotic membrane bioreactors, FO membrane helps to reject P to one side of a collection tank, while the MF/UF membrane permeates it for final recovery of P without the need for any addition of calcium or magnesium ions. Further, other rejected solutes in the FO system are transported into the bioreactor for final extraction using MF, which also enables lowering the salt accumulation in the bioreactor. Electrodialysis (ED) is one of the versatile methods which have had its prime role in heavy metals remediation of pollutant streams including industrial effluents and sewage sludge. Recently studies are investigating ED for direct P recovery, while being integrated with biological reactors to ensure both P availability and to make use of great fertilizer value of final sludge solids. The present challenges of ED including membrane fouling and increased electrical resistance (translating into higher operating/maintenance costs) could be effectively met by combining ED with anaerobic biological process, which stimulates the P release. Ion exchange membranes are known for its synergistic mechanism of membrane separation with selective ion-exchange capacity. Extensive potential of the ED has been utilised to separate phosphate from waste/sewage sludge.

Fig. 4 ED and MDC approaches for combining Mg recovery with desalination.

Combining Mg recovery with desalination systems

In order to maximize the production of Mg, membrane technology is considered a leading viable option, due its established popularity in the field of desalination. Wide spectrum of CRMs are found in sea water, yet commercial scale recovery remains a major barrier due to its low concentrations upon recovery. Whereas, industrially processed effluents are considered as one of the richest sources of inorganic salts/minerals, thus shifting the need for CRMs recovery towards effluents coming from desalination and wastewater treatment units. The paradox in combining minerals recovery with desalination, is that water is both a human necessity, but also a waste product in the mining industry. Likewise the desalination industry have seen their mineral-rich stream as waste, during the production of clean water. By combining these two industries in 'mining from the sea', many synergies can be obtained. The interesting objective of recovering minerals from the sea might actually partly aim to reduce the problem of brine disposal in desalination. Moreover, as an intriguing, positive side effect, it can contribute to the conventional mining industry, thus reducing mineral depletion. Several methods are emerging for mining valuable minerals on both individual and combined basis among which majorly employed methods include solar evaporation, electrodialysis (ED), and membrane distillation (MD)/membrane distillation crystallization (MDC) (Loganathan *et al.*, 2017). Schematic of the process flow diagram employing ED and MD with crystallizer systems for Mg recovery is shown in Fig. 4.

Membrane distillation

Growing research interest in zero liquid discharge (ZLD) technologies have driven the importance of treating RO concentrate, as it is considered as one of the waste resources to recover magnesium salts (Chung *et al.*, 2017). Research studies dealing with the treatment of emerging RO concentrate are to develop cost-effective methods to minimize the potential impacts on the environment. This will also offer alternative strategies to viably extract available salts, and to recover purified water. Several strategies have been adopted for the treatment technologies of RO brines and multiple review papers have also been published in the last decade (Subramani and Jacangelo, 2014; Jensen *et al.*, 2019).

Second major component of RO brine is magnesium and mostly the elements remain in the form of sulphates than carbonates. Major obstacle lies on the presence of calcium, either as CaCO_3 or CaSO_4 , both of which affects the membrane performance due to its poor solubility. Despite having no direct influence of Ca^{2+} present in seawater on Mg recovery, its impact is indirect on the efficiency of struvite recovery due to calcium phosphate formation. However, association of calcium carbonate (CaCO_3) with Mg results on the production of Dolomite ($\text{CaMg}(\text{CO}_3)_2$), which represent one of the primary natural sources of magnesium production.

Membrane crystallization

In a typical reactive crystallization, magnesium salts can be precipitated by means of hydroxyl radicals. Cationic form Mg^{2+} form can further be obtained based on electrodialysis mechanism. In the reactive hybrid process, integration of ion exchange membranes enables the development of Membrane Crystallizer Reactor (MCR) wherein IEMs are in selective contact with the alkaline reagents. In MCR, precipitation reaction occurs between brine and alkaline solution with no direct contact which is in contrast to conventional reactive crystallization. Moreover, indirect contact of IEMs with two different electrolyte solutions reduces the risk of co-precipitation of by-products thus enhancing the recovery efficiency. MCr was applied in an integrated system working on NF and RO brine for the recovery of sodium and magnesium. Introduction of NF is required to separate bivalent and monovalent ions, thus providing that

magnesium can be recovered from the NF retentate and sodium from the RO retentate, since it highlights that MCr can control/tune the polymorph selection, thus increasing the product value and minimizing the post-treatment.

Electrodialysis

In contrast to P, only scarce Mg sources are available from struvite or municipal wastewater, thus driving the need for fractionating Mg^{2+} from seawater. Hence, ED takes its role by combining the standard cation-exchange membranes, and monovalent selective cation-exchange membranes, for selective fractionation of Mg^{2+} from various side-streams rich in divalent ions (not limited to bittern, sea water, brucite, RO brine, and NF retentate). Seawater, containing substantial Mg^{2+} , is regarded as one of the leading potential resources offering the combination of desalination for product water treatment along with Mg^{2+} recovery.

Strategies to Maximize Mg and P Recovery

Integration of Mg and P Recovery Process- Closing the Loop Approaches

An integrated approach of bringing together various membrane processes having lower footprint may be significant to extract one or more valuable minerals, in particular Mg and P from seawater/brine effluent, and sewage wastewater respectively. Struvite, one of the potential secondary raw materials for both soluble P and Mg, can be recovered from wastewater based on various strategies. Membrane technologies employing advanced osmotic membrane reactors (OMR) as a stand-alone process (or integrated with other filtration processes like microfiltration/ultrafiltration) are now viewed as viable options for both P recovery and the production of clean water.

Design of a continuous and closed loop system for the recovery of valuable minerals like P and Mg from waste and renewable resources would be the challenging implementation steps for waste treatment or desalination. Process intensification is gaining more focus to mitigate against the issues related to CRMs depletion, water shortage, global warming, and waste recycling. Membrane processes closely match the current requirements of process intensification, for its energy-efficient separation routes when compared with conventional separation technologies. Membrane separation processes are already recognized as the best available technologies, allowing easy retro-fitting to most of the available processes to contribute to sustainable development.

For instance, current products such as membrane bioreactors (MBRs), primarily use for wastewater treatments, membrane-assisted crystallization, condensation and distillation, are based on the concept of facile redesigning of conventional energy-intensive separation methods. The interesting results achieved with these new technologies could overcome the limitations in recycling strategies. A relatively high P concentration combined with relative low organic matter content can be achieved by stimulating release of P from secondary sludge using volatile fatty acids (VFAs) under anaerobic conditions. Extracting P from the resulting liquid phase of the sludge will result in less fouling of the membranes and subsequently higher efficiency of P extraction.

By judicious selection of the draw solute for the operation of OMR, it is quite feasible to integrate hybrid MF/UF-OMR system into the tertiary wastewater treatment phase, wherein retentate stream of nanofiltration (NF) permeate or reverse osmosis (RO) retentate system containing MgCl_2 helps to enhance ionic strength and precipitation potential for P recovery (Ashley *et al.*, 2016). With pH adjustment greater than 8, P could be precipitated directly recovered from MF permeate without requiring any inorganic salts. With pH adjustment greater than 8, P could be precipitated, directly recovered from MF permeate, without requiring any inorganic salts. The feasibility of using sea water as a draw solute for P recovery using hybrid MF-OMR, followed by separation of Mg by electrodialysis would be gaining greater potential in terms of economics and process integration (Joo and Tansel, 2015). A typical process flowchart illustrating the concept of simultaneous recovery of both P and Mg and the integration potential of sea water RO (SWRO) brine, a concentrated stream of concern from desalination systems being used as a draw solute for operating FO as shown in Fig. 5.

Pre-Treatment Approaches

For integrated process design of advanced technologies for CRM recovery, pre-treatment strategies play a crucial role as most of the CRM recovery is aimed from secondary waste resources/ raw materials. Specifically to recover P and Mg, several methods including acid, alkaline, electrodialytic and ultrasonic, incineration have been studied, yet it is challenging to choose appropriate pre-treatment to best exploit the efficacy of entire recovery system. Despite many methods can significantly accelerate the phosphorus release during the sludge disintegration process, it is indispensable to choose cost-effective and efficient methodology. Most of the conventional stand-alone methods are cost intensive due to high energy inputs and/or substantial chemical requirements which might limit its largescale application. Furthermore, those methods certainly pose negative consequences on environment. Therefore, a cost-effective, efficient and environmentally friendly treatment method to enhance phosphorus release from wastewater is needed. For instance, mineralization of struvite or whey (dairy by-product) is quite complex due to the presence of various inorganic minerals/materials. Herein, implementation of simple and efficient pre-treatment steps could play a major role in removing the valuable minerals which would rather hinder the efficiency of further downstream processing. In lactic acid production process from dairy by-product streams, $\text{Ca}(\text{OH})_2$ precipitation has proven as an efficient pre-treatment step in recovering CaPO_4 while enhancing the production efficiency of lactic acid from whey permeate (O'Brien *et al.*, 2018). Fig. 6 summarizes the series of advanced pre-treatment, intermediate and final steps being adopted to enhance P release from wastewater and Mg recovery from seawater/brine.

Fig. 5 Process integration of wastewater treatment and desalination systems for simultaneous P and Mg recovery.

Fig. 6 Summary of advanced pre-treatment, intermediate and final processing steps specific to Mg and P recovery.

Biotechnological Approaches

Phosphorous can be recovered by biotechnological approaches based on two strategies. The first being microbial cell lysis for release of intracellular phosphate accumulated during biological nutrient removal process and the other is to induce the precipitation of phosphorous by influencing the pH conditions of the wastewater through metabolic pathways. In general, wastewater generated by domestic activities contains 5–20 g of phosphorous per cubic metre. The domestic wastewater is mostly treated using activated sludge processes. During the activated sludge process, the phosphates available in the wastewater are taken up by the microbial consortia present in the sludge to meet the metabolic needs of the cell. The excess phosphate taken up by the cell is stored as polyphosphate with in polyphosphate accumulating organisms. These organisms can be enriched by recirculating the activated sludge for accumulation of significant amount of phosphorous (up to 90%) (Wang *et al.*, 2017). Hence, waste activated sludge (WAS), a by-product of biological wastewater treatment process is gaining attention for recovery of phosphate due to its

availability and affordability. However, several challenges are need to be addressed such as low phosphorous release, economics of the entire process etc. Though the substrate is cheaply available, low recovery of phosphorous pose a serious challenge in recovery of phosphorous from sludge.

The first step in recovery of phosphorous from WAS is the release of phosphorous from intracellular and extracellular of the microbial cell. This step is typically done by microbial cell disintegration, yet efficient means of cell disintegration are required to meet the desirability. Various methods such as acid/ alkali hydrolysis, incineration, electro dialysis, ultrasonication have been investigated (Xu *et al.*, 2018). Though these methods can substantially increase the rate of release by disintegrating the cell wall and extra cellular polymeric substances, requirements of huge amounts of chemicals (acid/alkali), energy requirements affects the commercial viability and eco-friendly nature of these processes. Hence, identification of eco-friendly, energy efficient and affordable technologies to promote the recovery of phosphorous from waste activated sludge is need of hour. Few processes such as free ammonia treatment have been investigated for its biocidal activity and its application in sludge disintegration at lower concentrations. In this context, insights into energy efficient technologies need to be developed for enhanced recovery of phosphorous from microbial sludge produced during biological treatment processes.

On the other side, phosphorus can be precipitated/crystallized as hydroxyl apatite via changing the pH conditions and chemical dosing in wastewater (Baur *et al.*, 2008). However, this phenomenon could lead to clogging of the pipes if not properly controlled and can lead to economic loss. Therefore alternate strategies need to be explored for precipitation of phosphorous. Aerobic granular sludge process is one process that could be investigated as economically viable option for phosphorous recovery. The aerobic granular sludge process is recognized as a promising technology for treatment of wastewater at high organic loading rates. In addition to the removal of organics simultaneous nitrification and denitrification, phosphorous accumulation could be achieved. Precipitation of P has also been reported during activated sludge systems, however more insights into the process need to be developed. Calcium phosphate precipitation is a key contribution for P removal during Enhanced Biological Phosphorous Removal Processes (EBPR) and it is believed to increase the efficiency of biological phosphorous removal.

Future Perspectives and Technology Challenges on Sustainability

Globally securing sustainable access to CRMs is of high importance to meet the demands of industrialisation. However, with varying substitutability indices across the CRM spectrum, certain countries hold a monopoly on future, finite supplies. Currently the processing, recycling, reuse and recovery technologies of CRM are very complex, costly, and with very low yields. It is essential that new innovative technologies are implemented to provide efficient and scalable solutions to recover CRMs such as P and Mg from various complex resources. However, the biggest challenge to industry is to scale the innovative recovery technologies to produce commercially viable CRM's in a sustainable manner. A recent report highlighted that the use of CRM's in the EU economy is far from the ideal closed loop, circular economy (Mathieux *et al.*, 2017). That report also suggests a multi-component approach to tackle this global issue:

- (1) The need for a legislative framework governing processes to facilitate the extraction of CRMs from input flows.
- (2) Implement a sustainable policy on product life cycle - recycling, re-use, product lifetime extension, and new business models.
- (3) Ensuring up-to-date data is produced tracking CRM's across the life cycle (e.g., via The Raw Material Information System).

In order make these technologies industrially adoptable, it is essential to integrate traditional recovery processes with novel separation processes, such as membrane based technologies. The main advantage of membrane separation processes is that can offer relatively high yield CRM recovery, at low temperatures which minimises energy consumption. However to overcome other existing limitations of traditional membranes, more advanced membranes such as surface functionalised ion exchange membranes and electrospun membranes may offer a sustainable solution (Saranya *et al.*, 2018). These separation processes can further coupled with pre-treatment and bioremediation processes, resulting in relatively high yield and purity products. Clearly it is of critical importance that new processes that are developed are environmentally friendly with high energy efficiencies to create a global sustainable solution to this immediate issue.

Adoption of integrated process to catalyse a switch in the recycling and production transformation for CRMs and fossil-energy based materials could essentially help in building circular material flows on par with United Nations Sustainability development Goals. Promotion of sustainable technologies for sewage waste management and desalination enable P and Mg recycling respectively to ensure several sustainable aspects, however not limiting to depollution, renewability, demand-supply balance, food/environmental safety, macronutrient balance. It is also worth mentioning that one best solution does not preferably be suited for either P or Mg recovery as the process selection and integration depends on various factors including the geographical context, feed wastewater properties and so on. For example, membrane bioreactor combined with struvite precipitation is effective in terms of biosolids management, energy and P recovery. Further research and monitoring are strongly needed, including into improving organic contaminants removal in biosolids treatment, optimisation of energy recovery, and development and implementation of nutrient recovery processes. While focusing particular methodology for sewage/brine management and P/Mg recycling, the merits of various approaches specific to each stand-alone process must be brought together in the context of zero waste, quality control, transparency and effective product recovery. The European Commission has also estimated that P recycling methods could preferably replace 30% of Europe's P import for producing mineral based fertilizers. In the context of sustainability and renewability of Mg, it is worth considering the findings from a recent publication which highlighted that for every litre of

freshwater output, desalination plants produce approximately 1.5 litre of brine (Jones *et al.*, 2018). On the global level this equates to 142 million cubic meters of hypersaline brine discharged every day, as a magnesium rich waste stream. Unfortunately to date, the high economic costs and energy demands of brine treatment for the recovery of magnesium remains a significant barrier to more widespread application. The role of research and innovation is critical to realise a closed loop solution to this immediate issue, and membrane separation technical developments now offer a viable future path. Indeed, future vision on committing to 'sustainability' and 'zero waste' are focused greatly on CRM recovery from waste to stay well ahead of strict regulations on waste management and circular economy.

Biochar as Sustainable Reinforcement for Polymer Composites

Singaravelu Vivekanandhan, Virudhunagar Hindu Nadars' Senthikumara Nadar College (Autonomous), Virudhunagar, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Polymer composites reinforced with various fibre and particulate materials receive greater interest due to their physicochemical and functional properties, which significantly replace and substitute the traditional metal components in many potential applications with the added advantages of simple manufacturing ability and cost reduction (Pickering *et al.*, 2016; Giannelis, 1996). Various types of thermoset, thermoplastic and elastomeric matrix based composites have been extensively fabricated and explored for a wide range of industrial and consumer products. The increasing usage of polymer composites in various industrial sectors including, the wind energy, aerospace, packaging, construction and automotive lead to their market growth from the US \$ 72.58 billion in 2016 to the US \$ 115.43 billion by 2022, with the compound annual growth rate (CAGR) of 8.13%. Most of the polymer composites exist in the current market consist of petroleum based matrixes, which are nonrenewable and non biodegradable (MarketsandMarkets™). The issues arise during their post consumption disposal, which creates severe environmental impact. The emerging environmental concerns (i) in utilizing the petroleum feedstocks for polymer matrix, (ii) waste generation on their end of life disposal, (iii) greenhouse gas emission during the various stages of their value chain and (iv) the demand for sustainable manufacturing lead the researchers to work aggressively towards the alternate solution. As the result, biopolymers that includes the biodegradable polymers from petroleum feedstock and biodegradable/non- biodegradable polymers from renewable based resources have been invented and explored for various uses (Reddy *et al.*, 2013). In reinforcement perspective, various synthetic fibres such as glass, aramid, nylon, rayon, polyester, and carbon have been extensively explored in polymer composites. Non-renewable source and manufacturing cost of those synthetic fibres created the demand for renewable and cost-competitive substitute for composite fabrication. Thus, more attention has been paid by academic and industrial researchers in formulating new polymer composites containing natural reinforcements of fibres and particulates. Biomass reinforcement in polymer matrix offer, not only the environmental and economic benefits but also reduces the overall weight of the products compared with their glass fibre counterpart. Abundance of renewable resources lead to the effective utilization of various types of biomasses, which includes bio fibres (jute, sisal, cotton, cellulose), biomasses (switchgrass, miscanthus, sawdust), industrial coproducts (lignin, distiller's dried grains with solubles (DDGS), husks, shells) as the reinforcement in composite fabrication. Bio fibres can be classified based on the part of the plant, which includes, bast or stem fibres (jute, mesta, banana etc.), leaf fibres (sisal, pineapple, screw pine etc.) and fruit fibres (cotton, coir, oil palm etc.) (Wambua *et al.*, 2003). However, the biomass reinforcement creates few challenges such as, there moisture absorption behavior, limited thermal stability and poor compatibility with various kinds of polymer matrix, which limit the commercial potential of their composites. In the thermoplastic platform, bio-reinforcement creates the major issue of their thermal degradation during the extrusion process, which hampers the physicochemical performance of composite material due to the poor compatibility between thermally degraded biomass and the polymer matrix. Hence, the bio-reinforcement in engineering plastics is still challenging task as it has higher melt processing temperature ($\sim 220\text{--}300^\circ\text{C}$). Extensive efforts have been made in order to enhance the thermal stability of biomass, which includes water washing, chemical modifications and physical treatments. Recent advancement in that aspect is the thermal stabilization of biomasses, which can be termed as torrefaction, charification, carbonization, and graphitization that deals with the varying temperature and environments. Prior thermal history of biomass creates an enhanced thermal stability during their melt processing and the bio-reinforcement is possible in all the thermoplastics, including engineering plastics such as PET, PBT, PTT, and Nylon. Among the various thermo-stabilized biomasses, biochar receives significant attention in recent years and has been explored for composite applications. Biochar has been reinforced in a wide range of polymers from thermoset, thermoplastic and elastomeric categories. Conversion of biomass into biochar lead to the enhancement of their thermal stability creates new functional groups and reduces the density, which are the essential features for the efficient reinforcement. Increasing importance for the biochar reinforced polymer composite leads to this article, which deals with a brief summary of biochar based polymer composites and their properties. Further, it also discusses the biochar production, properties and their modification strategies for polymer composites along with their other potential applications.

Feedstocks, Process, Properties and Potential Applications of Biochar

Biochar is a carbonaceous solid product obtained from the biomass through the pyrolysis process along with syngas and biooil. The application potential of the biochar is depended on its inherent physicochemical and functional properties, which are influenced by many factors that include the nature of feedstock, type of pyrolysis process and pyrolysis conditions (temperature, heating rate, environment and resident time). Hence, it is necessary to understand the feedstock- process- property co-relationship in order to meet the demand for the specific application.

Feedstock for Biochar Production

Biochar has been produced from various biomass sources, which can be categorized into (i) agro/forestry residues (straw, stover, stalk, bark and wood chips), (ii) marine products (micro/macro algae), (iii) industrial coproducts (lignin, DDGS, hull/husks, oil

cakes, coffee chaff/ground, nut shells, tomato/grape/apple pomace, seeds and fruit peels), (iv) short term woody biomasses and energy crops (willow, poplar, miscanthus and switchgrass) and (v) municipal clean wastes (cardboard sheets and wooden pallets). In some cases, biochar also been produced through the co-pyrolysis of plastic wastes with various biomasses (Sharypov *et al.*, 2002). Most of the feedstocks that used for biochar production are undervalued, which creates various environmental issues on their storage and disposal. In most of the cases, the industries face economic burden due to the expenses for their effective disposal. Traditionally they have been explored as low cost fuel for energy application and creating new products through pyrolysis enhance their economic return and strengthen the waste based economy. Recent advancement in biochar utilization in many areas lead to creating an ever-increasing demand and causes the supply chain related issues, which can be addressed by exploring a diverse range of biomass for biochar production. Also, the biomass diversity and their availability vary region to region, which creates the necessity for biomass integration in char production in order to sustain their related technologies. Apart from the char production, it also helps to prevent the waste generation, reduces the greenhouse gas emission, creates more economic benefits and generates more employment opportunities (Cha *et al.*, 2016; Inyang *et al.*, 2016). Based on the nature of biomass, biochar production technology also varies in order to get more energy and cost efficiency. For intense, the physicochemical properties of the biochar are significantly impacted by the type of process and processing conditions.

Biochar Processing

The three major thermochemical conversion of biomass are the combustion/incineration (decomposition of biomass through complete oxidation), gasification (partial oxidation of biomass to get hydrocarbons), and pyrolysis (degradation of biomass without oxygen or inert atmosphere), which results in bioenergy, biofuels, biochemicals, and other value-added products (Yin, 2012; Motasemi and Afzal, 2013). Among them, pyrolysis has been explored for the production of biochar along with syngas and biooil. In biochar production, the critical factors are the yield and carbon content, which are controlled by the pyrolysis process. Various processes, which includes direct thermal pyrolysis (DTP), microwave assisted pyrolysis (MAP), plasma assisted pyrolysis (PAP) and hydrothermal carbonization (HTC) processes have been extensively used for the biomass pyrolysis/carbonization in order to get pyrolytic products such as syngas, biooil and biochar. The char product obtained from HTC process often called as hydrochar. Direct thermal pyrolysis process can be further classified into following three categories, (i) slow pyrolysis-lower heating rate of the biomass, (ii) fast pyrolysis- higher heating rate of the biomass, (iii) flash pyrolysis - exposure of biomass in heat for very short span of time i.e., few seconds (Goyal *et al.*, 2008). In this process, electric heaters or flame are employed as the source of heat. In order to enhance the carbonization uniformity and efficiency with a reduced duration other energy sources, which are based on microwave irradiation and plasma exposure have been introduced for the pyrolysis of biomass. The microwave is an electromagnetic radiation with the frequency ranging between 0.3 and 300 GHz and most of the laboratory microwave reactors operate at 2.45 GHz frequency (Motasemi and Afzal, 2013). In conventional thermal heating, the heat is transferred from the surface into the core of the material, whereas in microwave heating process the radiation can penetrate the materials and the heat can be produced throughout its volume. Microwave assisted biomass pyrolysis reduces the residence time due to effective heat transfer mechanisms, which leads to effective energy savings (Motasemi and Afzal, 2013). The plasma is consist of a large fraction of ionized gas and generates very high temperatures, which is capable of pyrolyzing the biomass and various organic waste streams. A diverse range of plasma sources are available, which can be effectively utilized for the pyrolysis of various biomasses (Chang, 2001). Plasma pyrolysis also results in the formation of gaseous and liquid hydrocarbons along with solid matter i.e. biochar (Huang and Tang, 2007). Thermal decomposition of biomasses employing the subcritical water is commonly known as hydrous pyrolysis or hydrothermal carbonization (HTC) (Libra *et al.*, 2011). The advantage of HTC process is the effective utilization of wet biomasses to turn into carbonaceous with relatively high yields comparing to the other carbonizing or pyrolysis processes. HTC is a green and sustainable process and a variety of biomasses can be converted into carbonaceous material in water at mild temperatures (Titirici and Antonietti, 2010).

Physics and Chemistry of Biochar

The thermal treatment of biomass alters its original physical and chemical structures through microscopic rearrangement, decomposition, pore formation, and crack generation, which are highly depend upon the chosen biomass and processing conditions (Downie *et al.*, 2009). Physical properties of the biochar that includes, density/porosity (pore volume and pore size distribution), specific surface area, hydrophobicity and water holding capacity, mechanical stability/grindability, electrical/electromagnetic properties, thermal stability/conductivity /heat capacity and agglomeration potential play important role in their application potential (Weber and Quicker, 2018). These properties highly depend on their chemical features, which can be assessed by means of atomic ratios, elemental composition, energy content, fixed carbon and volatile matter, functionality, pH value, ash content and self heating (Weber and Quicker, 2018). The density of the biochar can be correlated with the density of the parent biomass and it was observed that the higher density of the biochar could be obtained by using high density biomass as a feedstock (Byrne and Nagle, 1997). Increasing carbonization temperature increases the surface area up to 800°C. Further, the increment of carbonization temperature ranging between 800°C and 1000°C causes the reduction of surface area, which is due to the pore closing mechanism during the graphitization (Brown *et al.*, 2006). Carbonization process of biomass can improve the carbon content, which increases with increasing carbonization temperature and can be reached to ~90%. Irrespective of feedstock,

Fig. 1 Schematic representation of the various functional groups and the pore configuration of biochar. Reproduced from Lee, J., Kim, K.-H., Kwon, E.E., 2017. Biochar as a catalyst. *Renewable and Sustainable Energy Reviews* 77, 70–79.

biochar exhibits various functional groups on their surfaces, which includes carboxyl ($-\text{COOH}$) and hydroxyl ($-\text{OH}$) groups (Lee *et al.*, 2017). Fig. 1 shows the schematic representation of various functional groups of biochar and its pore configuration. Increasing pyrolysis/carbonization temperature decreases their surface functionalities. Biomass feedstock is slightly acidic or mildly basic, which exhibited the pH-value varies from 5 to 7.5. Pyrolysis process increases its pH-value, which can be reached 10–12, while the pyrolysis temperature is 500°C and above. The ash content of biochar is mainly dependent on the ash content in the parent biomass. It consists of various metal oxides, which includes SiO_2 , CaO , K_2O , P_2O_5 , Al_2O_3 and MgO (Weber and Quicker, 2018). All the above discussed properties are highly depend on the characteristics of biomass feedstock and the chosen carbonization process as well as their conditions, which can be precisely controlled through appropriate selection of materials and methods to achieve desired product properties. Understanding the process-property co-relationship is the critical aspect of biochar utilization for various applications.

Potential Applications

The unique and diverse physicochemical, morphological, structural and functional properties of the biochar lead them as suitable material for the various potential application. The application platforms of biochar can be classified into two categories such as traditional and technological. Traditional applications of biochar include soil amendment, energy production and carbon sequestration, whereas technological applications deals with catalytic, energy storage/conversion, activated carbon production, and environmental remediation. In addition to that biochar also been explored as the suitable candidate as the reinforcement for the fabrication of polymer composites.

Traditional applications

- (1) **Soil amendment:** The various roles of biochar in soil amendment is the immobilization of contaminant elements, sustained nutrient release, enhance organic carbon of the soil, alteration of pH and efficient water holding capacity (Uchimiya *et al.*, 2010). The biochars contain a wide range of nutrient with highly varying release rates, which impacts the overall soil quality and increases the crop yield significantly (Chan *et al.*, 2008). The biochar addition to the soil also stimulate the growth of soil microorganisms and lead to improved nutrient recycling, which are trapped in biochar (Steinbeiss *et al.*, 2009). It has been found that the biochar addition to the waterlogged paddy soil reduces the greenhouse gas (CH_4 and CO_2) emission (Liu *et al.*, 2011). The inclusion of biochar can effectively influence the soil-forming processes, which is an integrated action (accumulation, transformation, and translocation) of the soil constituents and can modify the soil morphology, pedogenic activity, and productivity (Richter, 2007). Altogether, biochar based soil amendment can be considered as the sustainable solution as it utilizes organic residues to generate biochar.
- (2) **Bio-Energy production:** Using raw biomass as fuel exhibits challenges like its high moisture content, lower energy density and poor grindability, which leads towards higher transportation cost. Converting biomass into biochar overcomes these disadvantages with higher energy density. It was observed that the biochar produced at $\geq 320^{\circ}\text{C}$ exhibits the H/C and O/C ratios as similar as to Collie coal (Abdullah and Wu, 2009). Efficient grinding is possible after the biomasses were converted into biochars leading to the increment of its volumetric energy density. Apart from the elemental carbon content, the ash concentration of biochar is the critical factor, not only in getting more calorific value but also the lifetime of the combustion chamber (Laird *et al.*, 2009). Hence, it's necessary to choose the biomass with less ash content for biochar production towards energy application. For the effective transportation of biochar with our any spillage, it must be pelletized or compacted.

Fig. 2 Schematic for the comparison between carbon and biochar sequestration. Reproduced from Lehmann, J., 2007. A handful of carbon. Nature 447, 143.

Pelletizing ability of the biochar can be increased by reducing the particle size or exploring the any environmental friendly binder (starch, natural gum, and lignin).

- (3) *Carbon sequestration*: The challenging climate change and global warming impacts can be reduced either by avoiding greenhouse gas emission or by eliminating the atmospheric CO_2 through excessive plant growth, which can act as CO_2 sequester (Lehmann, 2007). This kind of sequestration can be further enriched by converting the biomass into biochar through pyrolysis process (heating the plant biomass in oxygen less environment), in which biochar holds twofold higher carbon content comparing to their respective biomass (Baldock and Smernik, 2002). Producing biochar as the by product in pyrolysis industries during bioenergy production lead their relevant sequestration process with carbon-negative impact as shown in Fig. 2. Biochar sequestration can also consider as the robust and simple method as it does not require any scientific and technological advancement.

Technological applications

As the carbonaceous product, biochar receives great attention for various technological applications in order to substitute or replace the existing carbon materials that are obtained from petroleum resources. This will create a fundamental transformation of biochar production from waste management strategy into advanced materials manufacturing.

- (1) *Activated carbon*: The carbon material with high specific surface area and micro sized porosity, which are commonly produced from carbon rich and inorganic less feedstocks. Agro/forestry residues and various industrial by-products have been found as suitable raw materials for activated carbon due to their abundance and cost effectiveness (Ioannidou and Zabaniotou, 2007). Being a carbon rich product biochar can be explored for the production of activated carbon by employing various activation processes, which are based on physical, chemical and radiation platforms. Physical activation of biochar deals with its carbonization at elevated temperature in presence of various oxidizing mediums including CO_2 , steam, air and their mixtures. In the chemical activation process, the char products are finely mixed with the chemical activating agent such as KOH, ZnCl_2 , H_3PO_4 , and K_2CO_3 , followed by their carbonization at higher temperature and acid washing. Along with these, the microwave based activation process also been explored for the effective conversion of biochars into activated carbons. Selectivity of these processes is strictly based on the desired physicochemical and functional properties for specific applications.
- (2) *Catalysis*: Biochar has been extensively explored as the green and versatile catalyst for various applications including chemical synthesis, biodiesel production, tar reduction in pyrolysis process during bio-oil/syngas generation, microbial fuel cell

electrodes, deNO_x applications and pollutant degradation (Cha *et al.*, 2016; Lee *et al.*, 2017; Xiong *et al.*, 2017). Studies reviles that the catalytic performance of the biochar is comparable and even superior than the traditional resin, silica, and carbon-based catalysts (Xiong *et al.*, 2017). Various inherent properties of the biochar such as specific surface area, the assistance of micro/nano pores and their distribution and the –SO₃H site density play vital role in the catalytic performance of biochar. The catalytic activity of the biochar is highly dependent on the nature of biomass, biochar generation method and their conditions, and the pre/post treatments of the biochars (Lee *et al.*, 2017). Post treatments-post activation and oxidative acid treatment of the biochar play significant role in creating new functional groups, which can enhance the catalytic activity (Cha *et al.*, 2016; Anstey *et al.*, 2016). Selection of biomass, pyrolysis process, processing parameters are the key factors to get desired properties for biochar as the suitable catalyst for the specific application.

- (3) *Energy storage and conversion*: Carbon materials including, carbon black, carbon nanotubes, graphene and carbon fibres have been extensively used in energy storage and conversion devices such as batteries and supercapacitors (Zhang and Zhao, 2009). Along with these, biochar also receives increasing importance due to its unique physicochemical properties, surface area, porosity, structural stability during long term cycling performance and diverse morphological features. Pristine and modified forms of biochars have been explored as an anode material for various lithium batteries including lithium-sulfur, lithium oxygen and lithium-selenium (Zhang *et al.*, 2015; Gu *et al.*, 2015; Li *et al.*, 2016). In the electric double layer capacitor (EDLC), biochar products have been explored as the electrode material, which showed improved electrochemical performance (You *et al.*, 2017). Along with these, the biochar based polymer composites fabricated with polyaniline and polypyrrole also explored in fabricating supercapacitors.
- (4) *Environmental remediation*: Carbon materials exhibit excellent performance in various environmental remediation activities, which includes the immobilization of heavy metals, absorption of dyes/organic contaminants, and the removal of odor from water/air (Ahmad *et al.*, 2014). Biochar plays vital role in the above mentioned applications due to its porous structure and higher specific surface area. A wide range of metal impurities (Pb, Ar, Cr, Hg and Cd) (Inyang *et al.*, 2016), organic dyes (methyl orange), and chemical components (dichloro-diphenyl-trichloroethane (DDT), tetracycline (TC) (Liu *et al.*, 2012), polycyclic aromatic hydrocarbons (PAHs) as well as inorganic compounds (nitrate, ammonium, and phosphate) (Yao *et al.*, 2012) have been effectively removed from the aqueous medium by employing biochar. Further the activation process (physical, chemical, and radiation) of biochar enhances its porosity and active surface area, which improves its overall absorption performance. Being cost effective and greener product, biochar can have a great potential for environmental remediation application. The mechanism behind the absorption of inorganic contaminants by biochar is schematically shown in Fig. 3 (Ahmad *et al.*, 2014).

Biochar as Sustainable Filler/Reinforcement in Polymer Composites

Carbon materials including, carbon fibres, carbon black and carbon nanostructures (carbon nanotubes, graphene) have been widely explored as filler/additive/reinforcement for composite fabrication (Coleman *et al.*, 2006; Chand, 2000; Kim *et al.*, 2010; Huang, 2002). Apart from the reinforcing effect, those carbon materials also provided various functional properties that include electrical conductivity, EMI shielding and UV filtration. As a green and sustainable alternative, biochar receives great attention as efficient reinforcement in polymer composites for various matrix systems.

Thermoplastics

The interesting aspect of biochar utilization in composite fabrication is their feedstock diversity, which offers biochar with a wide range of structural, morphological and functional properties. Biochar obtained from various renewable resources were explored as reinforcement for thermoplastic matrix systems employing melt extrusion process. Polypropylene (PP) has been widely explored as the matrix for the fabrication of biochar reinforced composites. The biochars obtained from various bio-feedstocks such as agro/forestry reduces (hardwood (DeVallance *et al.*, 2016), bamboo, date palm tree wastes (Poulose *et al.*, 2018)), perennial grasses (miscanthus (Behazin *et al.*, 2017a)) industrial coproducts (lignin), organic wastes (landfill pine wood (Das *et al.*, 2017), sawdust, sewage sludge, and poultry litter (Das *et al.*, 2016b)) have been extensively explored for composite fabrication. It has been found that the surface area of the biochar play a significant role in the thermal and mechanical properties of composite material (Das *et al.*, 2016a). It has been observed that biochar reinforcement in PP not only enhance the mechanical properties but also improves its thermal stability/insulation properties and water absorption /thickness swelling performances (DeVallance *et al.*, 2016; Das *et al.*, 2016a). In order to enhance the mechanical properties of the biochar reinforced PP composites, researchers also explored the modification of matrix by incorporating an elastomer named poly(octene ethylene) (PEO). Also, the addition of compatibilizer, which enhances the interfacial adhesion between biochar and PP/PEO matrix, which results in the significant improvement of stiffness and toughness (Behazin *et al.*, 2017b). Along with the PP, polyethylene (PE) also been explored as the matrix for the reinforcement of biocarbon (biochar/charcoal) to fabricate biocomposites with the improved physicochemical properties (You and Li, 2014; Chen *et al.*, 2016; Li and Li, 2014). Very few research works also available for the reinforcement of biochar in polyvinyl alcohol (PVA) matrix in order to enhance their performance (Nan *et al.*, 2016; Nan and DeVallance, 2017). It was found that the reinforcement of biochar made of mixed hardwood into PVA matrix leads to having the similar electrical

Fig. 3 Schematic of mechanisms of biochar interactions with inorganic contaminants. Reproduced from Ahmad, M., Rajapaksha, A.U., Lim, J.E., et al., 2014. Biochar as a sorbent for contaminant management in soil and water: A review. *Chemosphere* 99, 19–33.

conductivity performance as most of the CNTs and graphene based PVA composites (Nan et al., 2016). The wood-derived biochar reinforced PVA composite was used for the pressure sensor applications (Nan and DeVallance, 2017).

As the demand for biobased polymers increases due to the increasing environmental concern in using PP and PE, the polylactic acid (PLA), which is commonly derived from corn receives greater attention in recent years for various potential uses (Pang et al., 2010). The challenge in PLA based polymer technology is the enhancement of its thermal, mechanical and thermomechanical properties in order to substitute or replace traditional PP based materials that are available in the consumer market. Effective reinforcement is one of the possible ways and hence various synthetic and natural reinforcements have been performed to achieve desired properties. Biochar obtained from bamboo (Ho et al., 2015) and Kudzu biomasses (Salak et al., 2015), also been explored as the renewable reinforcement for PLA. Bamboo biochar /PLA composite showed the improved mechanical properties and compost degradation rate. The thermally treated Kudzu biomass improved the water resistance of obtained PLA biocomposite. Pre-thermal history of biochar exhibits higher thermal stability of biomasses (~500°C), which can be reinforced even in engineering plastics, which exhibit higher melt/processing temperatures. Carbonized biomasses of lignin, miscanthus fibres have been respectively reinforced in the engineering plastics of poly (trimethylene terephthalate) (PTT) and polyamide 6, 10 (nylon) (Myllytie et al., 2015; Ogunsona et al., 2017a). It was observed that the biocarbon obtained at lower temperature (500°C) showed better affinity with nylon matrix and hence improved the impact strength of the composite (Ogunsona et al., 2017b). Fig. 4 schematically shows the affinity of biochar prepared at 900°C and 500°C with nylon matrix. The particle size, size distribution and shape of the biochar play a vital role on the composite properties. Particular with nylon, it was observed that the impact strength was improved with decreasing particle size (Ogunsona et al., 2017a). In another study, it was found that the biochar incorporation into nylon 6 matrix leads to the increment of the melt viscosity of the composite, which can be manipulated by the biochar particle size (Huber et al., 2015).

Apart from the individual polymer matrix, binary and ternary polymer blends also been explored as the matrix for biochar reinforcement. Poly(trimethylene terephthalate) (PTT) and poly(lactic acid) (PLA)PTT-PLA blend matrix was explored by Nagarajan et al. (2016) for the effective reinforcement of miscanthus-based biocarbon. They have investigated the effect of biochar size on the

Fig. 4 Schematic representation of the biochar affinity with nylon. Reproduced from Ogunsona, E.O., Misra, M., Mohanty, A.K., 2017. Impact of interfacial adhesion on the microstructure and property variations of biocarbons reinforced nylon 6 biocomposites. *Composites Part A: Applied Science and Manufacturing* 98, 32–44.

performance of composite and found that the increasing particle size slightly decreases their mechanical properties (tensile and impact), which can be improved by manipulating processing conditions (mold temperature) and incorporating chain extender. [Snowdon et al. \(2017\)](#) reported the miscanthus-based biocarbon reinforced ternary blend (Polypropylene/Poly (lactic acid)/Poly (hydroxybutyrate-co-hydroxy valerate)) composite, which showed the reduced tensile and improved flexural/impact properties. Along with the blending the co-injecting molding of biochar reinforced PTT/PBT as a core with polybutylene succinate (PBS) and polybutylene adipate terephthalate (PBAT) skin ([Mohanty et al., 2015](#)). The obtained co-injecting molded composite showed a slight increment in the tensile and flexural modulus. It was suggested that the core made from biochar reinforced PTT/PBT cause the poor tensile and flexural properties and the skin made out of PBS and PBAT lead to having higher impact strengths. [Codou et al. \(2018\)](#) investigated the effect of particle size and morphology of the miscanthus based biochar on the performance employing Maleic anhydride grafted PP (MAPP) compatibilized blend of nylon 6/polypropylene as the matrix (PA6/PP/MAPP). The particle size reduction of biocarbon influences the viscoelastic and thermo-mechanical performance of the fabricated biocomposites. [Fig. 5](#) shows the SEM micrograph of the pristine and ball milled biocarbon (for 4, 12, 18 and 24 h) reinforced PA6/PP/MAPP biocomposites along with the matrix. It was observed that addition of biocarbon inhibited the PP droplet formation (which is observed for the matrix in [Fig. 5\(f\)](#)) and no PP droplets are noticed after the reinforcement of biocarbon ([Codou et al., 2018](#)).

Further, the biochar has also been hybridized with other natural reinforcements such as wood fibre and the resulting hybrid composites exhibit the benefits of both the reinforcements ([Das et al., 2015a](#)). [Das et al. \(2015b\)](#) reported the fabrication of landfill pine wood based biochar and wood reinforced PP composites employing twin screw co-rotating extruder followed by injection molding. Through this work it was identified that the addition of biochar as a hybrid reinforcement along with wood in PP matrix lead to the better mechanical and thermal properties ([Das et al., 2015b](#)). [Andrzejewski et al. \(2018\)](#) reported the fabrication of polycarbonate biocomposites reinforced with the hybrid reinforcement of recycled carbon fibre and biocarbon. The obtained results confirmed the positive impact of biochar hybridization with carbon fibre. The composites made of 10% rCF and 10% biochar as hybrid reinforcement showed 270% improvement in the tensile strength and the 35% enhancement in the modulus with reference to the 20% pure biochar composites. The biochar hybridization will effectively create a new material choice with improved composite performance. [Fig. 6](#). shows the tensile and flexural properties of PC based recycled carbon fibre/biochar hybrid composites ([Andrzejewski et al., 2018](#)).

Thermosets

Thermosets are the polymeric material, which is highly cross-linked and can be cured by employing heat, pressure, and light irradiation. The most common classes of thermosets are phenolic, epoxy, polyurethane and polyester resins, which can be produced from either petroleum or natural resource based monomers (Raquez *et al.*, 2010). Among them, the epoxy resins, which are extensively used in many applications including aerospace, automotive, sports, constructions, and electronics due to their superior mechanical properties, chemical resistance and structural stability. However, the challenging issue for

Fig. 6 Tensile and flexural analysis results of PC based recycled carbon fibre/biochar hybrid composites. Reproduced from Andrzejewski, J., Misra, M., Mohanty, A.K., 2018. Polycarbonate biocomposites reinforced with a hybrid filler system of recycled carbon fiber and biocarbon: Preparation and thermomechanical characterization. *Journal of Applied Polymer Science* 135, 46449.

thermoset is their intrinsic brittleness, which can be improved by reinforcing various fibre and particulate materials. Reinforced thermoset composite exhibits the enhanced mechanical properties including the impact strength and hence a wide range of fibrous and particulate materials with natural or synthetic origins have been explored as reinforcement for composite fabrication. The char products of plastic waste, wood shaving and pine cone was explored for the fabrication of epoxy composites with the loading of 5–30 wt% (Ahmetli *et al.*, 2013). Superior tensile properties was observed for the composite reinforced with waste plastic char. The enhanced thermal stability was noticed for the composite made with pine cone char due their shielding effect (Ahmetli *et al.*, 2013). Fig. 7. shows the SEM images of the fracture surface of pure chars of plastic waste (PWC), pine cone (PCC) and wood shavings (WSC) along with the tensile properties of their reinforced epoxy resin composite (d). The biochar derived from china poplar and pine cone has been reinforced with epoxy resin (based on the diglycidyl ether of bisphenol-A) by varying the biochar loading (Oral, 2016). The effect of biochar loading on the elastic properties of epoxy resin/biochar composite was investigated by employing ultrasonic pulse echo overlap (PEO) method. It was observed that the increasing biochar content increases the ultrasonic velocities and effective elastic properties

Fig. 7 SEM images of the fracture surface of pure chars of plastic waste (a), pine cone (b) and wood shavings (c) along with the tensile properties of their reinforced epoxy resin composite (d). Reproduced from Ahmetli, G., Kocaman, S., Ozaytekin, I., Bozkurt, P., 2013. Epoxy composites based on inexpensive char filler obtained from plastic waste and natural resources. *Polymer Composites* 34, 500–509.

(Oral, 2016). In another work, the permittivity and conductivity of the pristine and activated biochar reinforced epoxy resin composite were investigated. It was found that the composite made with the activated biochar showed enhanced performance (Giorcelli *et al.*, 2016). The biochar obtained from maple wood biomass by pyrolyzing at the higher temperature of 950°C was reinforced with epoxy resin. Mechanical and electrical behavior of the fabricated epoxy resin/biochar composite was compared to the composites made with the carbon black and multiwall carbon nanotubes reinforcement (Khan *et al.*, 2017). The mechanical properties of the composite material were increased for the 2% of biochar reinforcement and exhibited better performance up to 20%, however, showed inferior properties in the plastic zone (Khan *et al.*, 2017). It was also observed that the tensile behavior of the epoxy resin composites reinforced with 4 wt% of MWCNTs and 20 wt% of biochar (maple wood) are similar (Savi *et al.*, 2017). Along with this, the miscanthus biochar reinforced epoxy resin, poly(furfuryl alcohol) and poly(propylene carbonate) composite also fabricated and the statistical approach was made employing ANOVA to find the correlation between the composition and mechanical properties (Mashouf Roudsari *et al.*, 2017).

Elastomers

Elastomeric materials originated from natural and fossil resources have been extensively used as their pristine and reinforced forms. Increasing the reinforcement of rubber material increases various properties, which includes tensile/tear strength, stiffness, modulus, and rupture energy. A wide range of reinforcements, which belongs to minerals, natural fibres and carbon materials have been explored for the enhancement of elastomeric materials. Among them, carbon black, obtained from the petroleum resources, has been extensively used to fabricate rubber composites due to its desired physicochemical properties. As the demand for sustainable materials that are fabricated from renewable resources and waste streams increases day by day, there is a drive for finding an alternative to carbon black. Being a carbonaceous material with the renewable origin, biochar has found great potential in the fabrication of elastomeric composites as green and sustainable reinforcement. The modified biochar has been effectively reinforced in SBR showed the enhanced tensile properties. Corn stover based biochar was hybridized with corn starch and corn flour for the reinforcement in carboxylated styrene–butadiene as the rubber matrix

(Peterson, 2012). The obtained hybrid rubber composite loaded with 3:1 ratio of cornstarch: biochar showed efficient reinforcing effect, which lead to have better toughness, tensile strength and elongation than the carbon black counterpart (Peterson, 2012). Woody waste feedstock based low ash content biochar was hybridized with carbon black (CB) as filler for styrene-butadiene rubber (Peterson, 2013). At higher loading, carbon black reinforced SBR showed better performance, however at 10% total filler with 25%–50% biochar resulted in composite materials with enhanced mechanical performance compared to those with 100% carbon black filler. The biochar obtained from bricwood, which showed high carbon content (89%) and less ash content (1.8%) was reinforced with styrene-butadiene rubber (SBR) and the obtained composite material showed superior toughness properties (Peterson *et al.*, 2016). Coconut shell based pyrolytic biocarbon also reinforced in styrene-butadiene rubber and their performance of the obtained composite materials was compared with the traditional carbon black based composite (Fan *et al.*, 2017). The obtained results reveal that the carbon black can be partially substituted with coconut shell char due to their favorable performance. It has been found that the birchwood biochar reinforced SBR composite could partially replace the carbon black composite without loss of toughness and tensile strength. The biochar of the dry hardwood obtained from fence-clearing activity was investigated for their surface modification with the heat treated starch in order to enhance the reinforcing effect (Peterson and Kim, 2018).

Modification Strategies of Biochar for Composite Application

Particle size and their distribution of the biochar play important role in their composite fabrication. Many studies found that the reduction of biochar particle size improves the reinforcing effect and enhance the composite performance. This can be achieved by employing various techniques including mechanical grinding ball milling processes. It was reported that the specific surface area of the miscanthus based biochar increased from 148 m²/g to 300 m²/g after the ball milling process for 2 h (Wang *et al.*, 2018). During the reinforcement of ball milled biocarbon with the PP matrix, it was found that the increased milling time increases the impact strength of the composite material.

The surface functionality of biochar is the key factor for the composite application, which influences the biochar-matrix interaction and enhances the load transfer properties. The effective load transfer mechanism play a significant role in improving the mechanical properties of composite materials. Hence the surface modification of biochar is very essential in order to improve overall composite performance. It has been reported that the surface modification of biochar obtained from bamboo biomass with HNO₃ and NaOH solution introduced amino and carbonyl/carboxyl groups respectively (Anstey *et al.*, 2016; Qian *et al.*, 2018). The functionalized biochar showed excellent interaction with PLA matrix and the obtained the PLA/bamboo-char composites result in the enhanced tensile and impact properties.

Conclusions

Biochar materials obtained from various biomasses have been explored as the effective reinforcing materials in composites for the various thermoplastic, thermoset, and elastomeric matrixes. A wide range of biomasses have been converted into biochar and explored as sustainable reinforcement for various polymer systems originated from renewable and petroleum feedstocks. The observed results indicate that the physicochemical and functional properties of the biochar can be precisely tuned by manipulating the various pyrolysis conditions in order to meet the requirement for specific composite. Hybridization of the biochar along with other kinds of reinforcement such as carbon fibres, carbon black and natural fibres exhibited improved composite performance than their individual counterpart. However, the composite technology based on the biochar reinforcement is in its infancy, which needs more advancement to compete with the composite materials that exist in the commercial marketplace. Extensive research effort needs to be devoted to the development of new biochar based composite systems. This will enable the effective product diversification for the possible commercialization of the biochar reinforced composite material.

Biomass Conversion to Selected Value-Added Chemicals Using Zeolites: A Review

Nageswara R Peela, Indian Institute of Technology Guwahati, Guwahati, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

The fossil resources are being utilized by human beings to advance technologically. There is no argument in saying that without fossil resources these advances are not possible in such a short span of time (about 150 years of discovery of these resources). However, this progress has been happening at the expense of rapid depletion of these resources as well as an adverse impact on the environment. Now it is time to think about the alternative, renewable and sustainable resources for generating electricity and synthesizing the fuels and chemicals. We have several such alternative resources such as biomass, solar, geothermal, wind, tidal etc. Among these, the biomass is an abundantly available and more evenly distributed resource in the world through which the solar energy is being stored in the form of chemical energy. Moreover, biomass is the only alternative and renewable resource which contains useful carbon atoms which can be converted to fuels and chemicals relatively easily. It has been suggested that the biomass be used for synthesizing the fuels and chemicals and other alternative resources be used for the generation of electricity. The biomass conversion to value-added chemicals is pursued as a greener, renewable, and sustainable approach to produce fine and pharmaceutical chemicals.

During acid catalyzed hydrolysis and dehydration of carbohydrates, the presence of lignin and inorganic metal salts may deactivate the catalyst. Therefore, it is advisable to remove these parts before processing the carbohydrates to value-added chemicals. Various methods (such as steam and CO₂ explosion, acid, and alkali treatment) have been used to separate the three components (cellulose, hemicellulose and lignin) of the biomass. The major portion of the lignocellulosic biomass is the cellulose (40–60 wt%). However, many pathways use fructose as the starting substrate to produce chemicals and fuels (Saravanamurugan *et al.*, 2017). Therefore, cellulose should first be converted to fructose. Two major steps (cellulose hydrolysis to glucose and glucose isomerization to fructose) in series have to be followed to convert cellulose to fructose. The research on the direct conversion of cellulose or even raw biomass to value-added chemicals is also speeding-up in recent years (Zhang *et al.*, 2017; Li *et al.*, 2016; Badgujar *et al.*, 2019).

The acid hydrolysis of cellulose takes place in three reaction steps: protonation of glycosidic oxygen, cleavage of glycosidic bonds and nucleophilic attack of water (Kang *et al.*, 2018). The cellulose hydrolysis step has been carried out using various catalysts such as acidic, enzymatic. The zeolite catalysts have also been used for this step (Hu *et al.*, 2015). Cellulose and hemicellulose could be depolymerized using hydrolysis reaction over zeolites. Various zeolites and metal encapsulated zeolites have been tested for the reaction (Shrotri *et al.*, 2018). Particularly, dealuminated zeolites showed good activity in hydrolysis reaction (Moreau *et al.*, 2000). Incorporation of hydrophobicity into the zeolites by dealumination also resulted in the better conversion and yields (Buttersack and Laketic, 1995, 1994). The dealuminated Sn-Beta zeolite with balanced Brønsted and Lewis acidity is demonstrated to be highly effective for sucrose (a non-reducing carbohydrate) to fructose conversion with high yields (Saravanamurugan *et al.*, 2017). Various properties of the zeolites such as micropore topology, mesoporosity, and acidity could significantly influence the hydrolysis process (He *et al.*, 2014). The hemicellulose hydrolysis is relatively a milder process as compared to cellulose hydrolysis.

Several studies have been carried out to understand the mechanism of glucose to fructose isomerization by homogeneous catalysis (with metal ions or acids) (Choudhary *et al.*, 2013; Nagorski and Richard, 2001; Pagán-Torres *et al.*, 2012), by enzymes (Toteva *et al.*, 2011) and by base-catalysis (Liu *et al.*, 2014). It has been observed that the base catalyzed reaction follows the proton transfer mechanism whereas the acid catalyzed reaction follows the hydride transfer mechanism. Significant work has been carried out by Davis' group to obtain insights on isomerization of glucose to fructose on hydrophobic, solid Lewis acid catalysts such as Sn-Beta and Ti-Beta (Bermejo-Deval *et al.*, 2012; Bermejo-Deval *et al.*, 2014; Nikolla *et al.*, 2011). It has been identified that the metal centers present in Sn-Beta and Ti-Beta act similar to the metal centers present in metalloenzymes towards this isomerization reaction (Moliner *et al.*, 2010). The authors proposed that the "metal-assisted intramolecular hydride shift" mechanism is responsible for glucose isomerization to fructose on these catalysts (Román-Leshkov *et al.*, 2010).

Zeolites are good catalyst systems for various processes where acid catalysis is involved. However, the microporosity is the major drawback of these materials in biomass processing as the reactants and products involved are bigger in size than the pore sizes of the microporous zeolites. Recently, researchers have demonstrated that hierarchical zeolites containing both micropores and mesopores are highly suitable for the biomass conversion reactions with enhanced activity (Kang *et al.*, 2013; White *et al.*, 2014; Moreno-Recio *et al.*, 2017). Both top-down (Nandiwale *et al.*, 2014a; Yu *et al.*, 2015) and bottom-up (White *et al.*, 2014; Zhu *et al.*, 2014) approaches have been used to synthesize the hierarchical zeolites. The top-down approaches, such as steaming, desilication, and dealumination, are straightforward and cheap. However, these may result in low pore-wall crystallinity which in turn may result in lower catalyst stability. Therefore, the bottom-up approach is more attractive.

The scope of this review is to summarize the recent literature on biomass (and its constituents: cellulose, and hemicellulose) to value-added chemicals using zeolites, zeotype, and functionalized zeolite catalysts. The major focus of this review is on the production of levulinic and lactic acids and their esters.

Carbohydrates to Levulinic Acid and its Esters

The levulinic acid (4-oxopentanoic acid) is a promising platform chemical with applications in several areas such as biofuels, cosmetics, agrochemicals, fragrances (Pileidis and Titirici, 2016). US DoE identified LA as one of the top 12 platform chemicals. The LA contains two functional groups, one is a ketone and the second one is acid. The bi-functionality of LA makes it highly reactive and suitable for transformation to other value-added chemicals (Badgujar *et al.*, 2019). According to the survey by the research and market survey, the LA market projected revenue by the year 2025 is \$ 57.6 million and its compounded annual growth rate is 15.4% (Badgujar *et al.*, 2019). LA could be produced from cellulose as well as from hemicellulose (Li *et al.*, 2019). However, the hemicellulose route involves the formation of furfural alcohol from furfural (by hydrogenation) which requires a metal catalyst and H_2 with moderate pressure. Therefore, conversion of hemicellulose to LA requires a bi-functional catalyst containing both acid and metal sites.

An early work reported the fructose conversion to LA over LZY zeolite catalyst at 140°C (Jow *et al.*, 1987). A maximum LA yield of 43 wt% with very low 5-HMF yield is obtained and is attributed to stronger dehydration ability of Lewis acid sites and the molecular-sieving effect of the LZY zeolite. Using Amberlyst-15, Son *et al.* (2012) reported a LA yield of 52% from fructose at 120°C for 24 h.

Acharjee and Lee (2018) tested a dual solid-acid catalyst (Amberlyst-15 and Sn-Beta) for the conversion of glucose to LA. Due to the availability of both the Lewis and Bronsted acid sites, the dual solid-acid catalyst shows higher yields of LA as compared to Amberlyst-15 alone. The Lewis acid sites available on the Sn-Beta favor the isomerization of glucose to fructose. Kumar *et al.* (2016) synthesized Ga-modified mordenite zeolites by the sonochemical method, used for the glucose conversion to LA and reported an LA yield of 60% in a reaction carried out at 175°C for 6 h. The authors emphasized that the synergism between the Lewis acid sites of Ga^{3+} and the Bronsted acid sites of MOR resulted in higher yields. Ramli and Amin tested a series of Fe/HY catalysts for the production of LA from glucose. The surface area, porosity and amount and type of acid sites are found to have a profound influence on the activity of the catalyst. Catalysts with higher Lewis acid sites are found to form humins and those with relatively high mesoporosity are found to exhibit decent LA yields. 10%Fe/HY exhibited the best performance with LA yields of 62% at 180°C in 180 min (Ramli and Amin, 2015a). The same group reported LA production from oil palm fronds with yields of 17.6% (Ramli and Amin, 2015b). The authors reported a stable operation up to five cycles without any significant Fe leaching. Suacharoen and Tungasmita (2013) reported an LA yield of 38% from glucose over 20% Ru/ZSM-5 catalyst. Yáaini *et al.* (2013) synthesized hybrid catalyst $CrCl_3$ /HY and tested for glucose to LA conversion. With 1:1 ratio of $CrCl_3$:HY, the authors reported an LA yield of 62% at 160°C in 180 min of reaction time.

Dumesic and co-workers used various catalysts (such as zeolites, Amberlyst-70) for the direct conversion of cellulose to LA. Using a mixture of 90% γ -valerolactone (GVL) and 10% water as a solvent, the LA yield over zeolites ZSM-5 and mordenite is 35%, while that over Amberlyst-70 is 69%. However, when pure water is used as a solvent the LA yields are significantly lower (2% over both the zeolites and 19% over Amberlyst-70). Therefore, it is understood that GVL plays a significant role in dissolving the cellulose into the reaction media and thereby enhancing the solid (cellulose) – solid (catalyst) interaction (Alonso *et al.*, 2013). Huber and his group used a two-step process for the conversion of cellulose to LA. In the first step, they have decomposed the cellulose non-catalytically and hydrothermally to the water-soluble LA precursors. In the second step, they converted the water-soluble compounds to LA and formic acid over Amberlyst-70 at 160°C. The maximum yield of LA is reported to be 28% of theoretical (Weingarten *et al.*, 2012b).

Hartono *et al.* (2016) used the corncob as a substrate for the production of LA over acid activated natural zeolite and reported a maximum LA yield of 262.4 mg/g of dried corncob. Yáaini *et al.* (2012) tested 10% $CrCl_3$ /HY for the conversion of empty fruit bunch and Kenaf biomass substrates to LA and reported 15.5 (29.2% theoretical) and 15 wt% (22.7% theoretical) LA yields, respectively. Krisnandi *et al.* (2019) synthesized hierarchical $MnOx$ /ZSM-5 and tested for the conversion of delignified rice husk to LA. The authors reported an LA yield of 16 wt% based on the cellulose weight after delignification.

The activation energies for glucose to 5-HMF and 5-HMF to LA reactions are reported to be 64 and 61 $kJ\ mol^{-1}$, respectively. Whereas, those for the conversion of glucose to humins and 5-HMF to humins are reported to be 76 and 70 $kJ\ mol^{-1}$, respectively (Ramli and Amin, 2016). This might highlight the fact that glucose to LA reaction is relatively more favorable than that of glucose or 5-HMF to humins. Weiqi and Shubin (2017) and Wei and Wu (2018) studied the kinetics over Cr /HZSM-5 and reported the activation energies for glucose dehydration and 5-HMF rehydration reactions to be 69.1 and 54 $kJ\ mol^{-1}$, respectively. From most of the kinetic studies reported in the literature, the activation energy of glucose to humins reaction is higher as compared to that of 5-HMF to humins, with both homogeneous (Weingarten *et al.*, 2012a) and heterogeneous (Ramli and Amin, 2016) catalysts. Moreover, the activation energy of glucose to the 5-HMF reaction is lower as compared to that of glucose to humins reaction. These data clearly indicate that the humins formation is favoured from the 5-HMF rather than from the glucose.

Researchers have explored the possibility of converting the C5 sugars (hemicellulose based) to LA. In a three-step process (xylose $\rightarrow$ furfural $\rightarrow$ furfural alcohol $\rightarrow$ LA), Dumesic and co-workers (Gürbüz *et al.*, 2012) reported an LA yields of up to 70%. However, when HZSM-5 is used as a catalyst the yield of LA is very low (15%). In another publication from the same group, they reported an LA yield of 75% from furfural alcohol (a derivative of xylose) over HZSM-5 with SiO_2/Al_2O_3 ratio 80 (Mellmer *et al.*, 2015). The authors also tested the effect of various solvents and found that a mixture of water and tetrahydrofuran (THF) with a THF:H₂O ratio of 4 gives the highest yield of LA and remains nearly constant with the solvent ration varied from 19 to 2. Sulfuric acid as catalyst showed a lower yield of LA (maximum 56% at THF:H₂O ratio of 19 and decreased with increasing the water content). A similar yield (56%) is obtained over HZSM-5 with a very low solvent ratio of 0.5. The authors attributed the higher yields at lower solvent ratio over HZSM-5 to the constant internal solvent microenvironment, which in turn is due to the hydrophobicity of the zeolite. Jeong *et al.* (2018) reported an LA yield of 43% from xylose over alkali treated HY zeolites.

Chamnankid *et al.* (2014) demonstrated that upon alkali treatment and formation of strong acid sites, the zeolite Y can be used for the direct conversion of xylose to LA with a maximum yield of 30%.

The major application of levulinate esters (LE), such as methyl, ethyl and butyl levulinate, is as a fuel additive (Climent *et al.*, 2014; Démolis *et al.*, 2014). In gasoline, they act as octane number boosters and in diesel they act as fuel extenders. Up to 5% of LE could be blended in conventional diesel fuel (Fernandes *et al.*, 2012). The other applications of LE are in industries such as flavoring, pharmaceutical, and fragrance (Zhang *et al.*, 2018). Research is being carried out to produce LE from various feedstocks such as LA, fructose, glucose.

Earlier studies reported esterification of LA with alcohols to produce LE. Fernandes *et al.* (2012) tested various zeolites (HUSY, HBEA, HMOR, HZSM-5, and HMCM-22) for the esterification of LA to ethyl levulinate (EL). HMCM-22 showed the highest conversion of LA followed by HUSY. The lowest activity is showed by HZSM-5. The data indicate that the topology of the zeolite plays an important role in imparting the activity. The zeolites with larger pores show higher activity owing to their ability to incorporate the large-sized transition states. Bokade and co-workers (Nandiwale *et al.*, 2013; Nandiwale *et al.*, 2014b; Patil *et al.*, 2014) synthesized various zeolite catalysts with varying mesoporosity and tested for LA to LEs conversion. The activity of desilicated H-ZSM-5 is higher as compared to its fresh counterpart. The activity is further increased when dodecatungstophosphoric acid is impregnated on to the desilicated H-ZSM-5 (Nandiwale *et al.*, 2013). The same desilicated H-ZSM-5 when used for LA esterification with different alkyl alcohols, the authors found that the activation energy decreases with the increase of alkyl chain. For example, the activation energy with methanol is 52 kJ mol⁻¹, whereas, that with n-octanol is 17 kJ mol⁻¹. The recyclability of the catalyst is good with only a marginal decrease of activity in six cycles (Nandiwale and Bokade, 2015). Lucas *et al.* (2019) synthesized silicotungstic acid supported on ALSBA-15, tested for LA to EL conversion. The catalyst shows an EL selectivity of 100% at an LA conversion of 87%.

Saravanamurugan and Riisager (2013) tested various zeolites for the direct conversion of carbohydrates to levulinate esters (methyl and ethyl levulinate). The authors observed that H-USY is a highly active zeolite among the tested. Various carbohydrates used in the study resulted in a nearly equal yield of methyl levulinate (50%). In another communication (Saravanamurugan and Riisager, 2012), the same group presented that the catalyst SO₃H-SBA-15 showed an improved ethyl levulinate yields of up to 57% from fructose at 140°C. The authors also showed that the catalyst is more selective to form EL as compared to the other zeolites (H-ZSM-5 and H-MOR) used in the study. The combination of Lewis and Brønsted acid sites (SO₄²⁻/ZrO₂ and Sn-Beta) shows a good yield of methyl levulinate (62%) from glucose at 170°C for 24 h (Jiang *et al.*, 2018). The similar yields have been reported with fructose and sucrose as substrate. The methyl levulinate yield is very low (<3%) over Na/montmorillonite (Mt) (Liu *et al.*, 2017). However, the yields increased significantly up to 60% upon exchanging the Na with metals such as Sn, Al, Cu and In (Liu *et al.*, 2017; Liu *et al.*, 2018).

Tang *et al.* (2018) used catalytic transfer hydrogenation for the conversion furfural to ethyl levulinate over a combination of Lewis and Brønsted acid catalysts (Zr-SBA-15 and ZSM-5). The tandem catalytic reaction produced EL with yields up to 55% in a reaction conducted at 180°C for 16 h.

Carbohydrates to Lactic Acid and its Esters

The lactic acid (LAC) formation from glucose starts with the isomerization of glucose to fructose. The formed fructose converts to glyceraldehyde by retro-aldol condensation. The glyceraldehyde after undergoing a few more reaction steps forms the lactic acid. The retro-aldol condensation and the dehydration (to form 5-hydroxymethylfurfural) reactions compete for acid sites. The Brønsted acid catalysts favor the dehydration reaction. Whereas, the Lewis acid catalysts increases the possibility of retro-aldol condensation occurrence. However, all the Lewis acid catalysts are not favorable for the retro-aldol condensation. For example, even though the H-Beta and H-ZSM-5 possess Lewis acid sites, the lactic acid formation is negligible over these catalysts (Marianou *et al.*, 2018). When Sn is impregnated/ion-exchanged on to these zeolites then lactic acid formation is observed. Effect of acidity of catalyst and the solvents on the production of lactic acid from glucose over Sn/zeolites is reported by Marianou *et al.* (2018).

Xia *et al.* (2018) recently tested a bimetallic catalyst loaded on beta zeolite for the lactic acid production from glucose and observed yield of 52% at a glucose conversion of >99% at 190°C for 2 h under ambient air pressure. The roles of individual metals are found by testing the intermediates as reactants. The lead plays an important role in promoting the isomerization and retro-aldol reactions. Whereas, tin plays a superior role in activating the dehydration of dihydroxyacetone, the hydration of pyruvaldehyde and the isomerization of pyruvic aldehyde hydrate. A clear synergism is observed over the bimetallic catalyst as compared to that over a catalyst containing the individual metals. The same group has utilized 3-aminopropyltrimethoxysilane functionalized Sn-Beta for the sucrose to LAC conversion and reported a 58% yield at complete conversion at 190°C for 4 h. The functionalized catalyst promotes the hydrolysis and suppresses the dehydration (to form 5-HMF) reaction (Kong *et al.*, 2018).

Murillo *et al.* (2014) demonstrated that the Sn-MCM-41 catalysts are highly efficient in converting glucose to methyl lactate (yield 43%) at 160°C for 20 h. From trioses, yield more than 95% could be obtained using Sn-Beta catalyst at very low temperatures of 40°C (Osmundsen *et al.*, 2012). Other catalysts (such as Sn-MCM-41, Sn-MFI, Sn-SBA-15) used in that study showed much lower activities as compared to Sn-Beta. A similar trend is observed with the sucrose as substrate at 160°C. Sn-Beta catalyst showed at least two times the higher yield of methyl lactate as compared to other catalysts. The reason for the lower activity of the Sn-MCM-41 or Sn-SBA-15 catalysts is their inability to promote the hydride shift reaction.

Holm *et al.* (2010) tested various metal (Ti, Zr, and Sn) containing Beta zeolite for the retro-aldol condensation of fructose, glucose and sucrose to alkyl lactates at 160°C for 20 h in methanol. The authors found that the Sn-Beta shows the best activity with a methyl lactate yield of 64% from sucrose. Whereas, over the same catalyst glucose and fructose results in a yield of 44%. The yields of methyl

lactate are lower over Ti-Beta and Zr-Beta catalysts as compared to that over Sn-Beta. The best activity over Sn-Beta catalyst is attributed to the stronger Lewis acid sites present on this catalyst. In the presence of other higher alcohols as solvents results in the formation of the corresponding alkyl lactates and with water as solvent lactic acid is formed, all-be-it, with lower yields. The methyl lactate is not forming at all over Al-Beta and Si-Beta, owing to the absence of Lewis acid sites. Tolborg *et al.* (2015) reported a higher yield (75%) of methyl lactate from sucrose when Sn-Beta is used along with alkali carbonates at 170°C. The authors found that alkali presence is inevitable, as in the absence of alkali the yields are very low (30%). The beneficial effect of alkali presence is also demonstrated with the other stannosilicate materials such as Sn-MCM-41 and Sn-SBA-15. The alkali present in the solution exchanges with the open sites in the stannosilicate materials to form 1,2-intramolecular carbon shift (1,2-CS) sites (Bermejo-Deval *et al.*, 2014).

The catalysts which do not promote the aldose-ketose isomerization would be beneficial for the retro-aldol reaction to produce the alkyl lactate selectively. With this notion and to reduce the reaction temperature, Orazov and Davis (2015) tested a combination of two catalysts for the production of alkyl lactate (or lactic acid) from ketohexoses. The catalysts which promote 1,2-CS (such as molybdenum oxide) and 1,2-intramolecular hydride shift (such as Sn-MFI) reactions are used. The authors demonstrated that the combined catalyst system ($\text{MoO}_3 + \text{Sn-MFI}$) is able to convert fructose to alkyl lactate with yields as high as 75% at a temperature as low as 100°C. However, the effect of substrate concentration is significant. The yield of alkyl lactate decreases significantly from 75% to 21% as the fructose concentration increases from 0.2% to 5%. Use of water instead of alcohol as a solvent also decreases the yield significantly (from 68% to 27%).

Mesoporous methylated stannosilicates are also used for the production of ethyl lactate from dihydroxyacetone (DHA) and reported a selectivity to alkyl lactate of > 99% (Vivian *et al.*, 2018). Yamaguchi *et al.* (2018) used a simple $\gamma\text{-Al}_2\text{O}_3$ catalyst containing both acid and base sites for the conversion of glucose to methyl lactate and observed yield of 34% at 100% glucose conversion at 160°C for 6 h.

Cellulose and raw biomass (Oakwood) have also been used as substrates in the production of methyl lactate (Verma *et al.*, 2017). While the methyl lactate yields from cellulose, glucose, and fructose are in the close range of 58%–67%, the order is as follows: $Y_C < Y_G < Y_F$. However, the yield from Oakwood is much lower (<10%). The high yields from the monomers and cellulose are due to the proper L/B ratio that is maintained by doping Ga onto the Zn/H-Y catalyst. Presence of a small amount of water in the reaction mixture drastically decreases the methyl lactate yield. For example, the methyl lactate yield from cellulose is decreased from 51% to 29% at 280°C when 10% of water is added to the reaction mixture. Adsorption of water onto the Lewis acid sites is cited as the possible reason for the decrease in yield.

The C5 carbohydrates have also been converted to lactic acid/alkyl lactate (Paksung and Matsumura, 2015; Yang *et al.*, 2016; Holm *et al.*, 2012). The hemicellulose monomers (C5 compounds) such as xylose, arabinose, and ribose are converted to methyl lactate over Sn-Beta and found that the xylose resulted in methyl lactate yields of 41%. As compared to C5 carbohydrates, C6 carbohydrates (fructose, glucose, etc.) give higher yields over the same catalyst and under similar reaction conditions (Holm *et al.*, 2012). However, over Zr-SBA-15, Yang *et al.* (2016) reported a similar methyl lactate yield of approximately 40%–44% from both C5 and C6 carbohydrates.

Summary

In summary, the zeolite and zeotype catalysts are highly active and selective for the production of levulinic and lactic acids and their esters. For glucose conversion to levulinic acid and its esters, it is observed that a catalyst containing a combination of Lewis and Brønsted acid sites (e.g., CrCl_3/HY) is highly beneficial in obtaining higher yields. Even the physical mixtures of the catalysts containing Lewis and Brønsted acid sites (e.g., $\text{SO}_4^{2-}/\text{ZrO}_2$ and Sn-Beta) gives impressive results. Kinetic analysis indicates that the humins formation is exclusively from 5-hydroxymethylfurfural. Therefore, catalysts for LA production should be chosen in such a way that the rehydration reaction favors over the condensation of 5-HMF to humins. Solvents and solvent+catalyst combinations also play a significant role in obtaining higher yields of LA/LE.

The catalysts which promote retro-aldol reaction over the aldose-ketose isomerization are beneficial for the production of lactic acid and its esters. The catalysts containing the sites that favor the 1,2-intramolecular carbon shift and 1,2-intramolecular hydride shift reactions demonstrate good yields of lactic acid esters.

Introduction

Worldwide annual plastics manufacturing is appraised to exceed 330 million tons by 2020, growing at a CAGR (Compound Annual Growth Rate) of 5.3% from 2014 to 2020 (Plastics market to reach \$ 654.38 billion by 2020), showing trillions of dollars regarding world economic returns. More than 40% of the plastics are used for packaging, and almost half of them are used for food packaging in the form of films, sheets, bottles, cups, tubs, and trays, etc (Rhim *et al.*, 2013). Petroleum resources are widely employed in manufacturing these polymers, which generate issues regarding both economic and environmental protection. After their beneficial life, it is preferable for the packing materials to biodegrade in a reasonable time without generating environmental problems. Though the synthetic plastic materials have been extensively utilized for the packaging of several kinds of food; they cause severe environmental issues because they are not readily degraded in the environment after use (Rhim *et al.*, 2013). So, there is an increasing trend to utilize environmentally friendly polymers with the aim of substituting non-degradable materials, thus lowering environmental pollution as a result of waste accumulation. To address environmental issues, and simultaneously increase the shelf life and quality of food, decreasing packaging waste has catalyzed the exploration of new bio-based packaging materials like edible and biodegradable films (Desobry and Debeaufort, 2011).

Nanotechnology is considered an essential tool for the improvement of advanced materials. By 2020 it is expected that nanotechnology will influence at least \$3 trillion of the worldwide economy, generating a request for 6 million employers in different production fields (Duncan, 2011). Nanoscience and nanotechnology applications in the agriculture, food sector and food safety are relatively recent compared with their use in cosmetics and personal care products (60%), paints and coatings, catalysts and lubricants, security printing, drug delivery and pharmaceuticals, medical therapeutics and diagnostics, energy production, molecular computing and structural materials (Shankar and Rhim, 2018a; Vasile, 2018). Over \$17.8 billion global investment was made in 2010 for research and development in nanotechnology, and this will grow to \$3 trillion by 2020. Food packaging sector counts for ~50% market value for all nanotechnology-enabled products with an annual growth rate of 11.65%. Through this global tendency, it is predictable that nanotechnology will offer the main drive in the progress of novel packaging applications systems for satisfying consumer's requirements.

Nanotechnology deals with the particle size of less than 100 nm at least in one dimension, and the nanosized particles show unique chemical and physical properties which are meaningfully diverse from the properties of macro-scale materials containing identical materials (Youssef *et al.*, 2013). Nanotechnology is mainly applied to extremely high gas barriers packaging materials with antimicrobial properties and nano-encapsulants for the delivery of aromas, flavors, or nutrients (Rhim *et al.*, 2013).

Bionanocomposites are believed to be one of the potential technologies that can be used to increase the storability of foods and to improve the present packaging technology, helping to ensure the microbial safety and the preservation of food from the influence of external factors (Fig. 1). Although extensive research is being undertaken at industry and academic levels, bionanocomposites in food packaging is still in the developmental phase. For the growth of bionanocomposites in food packaging at an advanced level, it is

Fig. 1 Application areas of nanotechnology in the food packaging sector.

essential to look at the complete life cycle of the packaging (from raw material extraction and production to usage and administration), integrating and balancing cost, performance, health, and environmental considerations. The multidisciplinary research is required in bionanocomposites-based food packaging area to overcome the barriers like safety, technology, regulation, standardization, trained workforce, and technology transfer to achieve the benefit for commercial products in the global market. Moreover, owing to the enormous growth application potential of bio-nanocomposites in food packaging, the emerging technology will be a hub of new employment opportunities because of degradable and eco-friendly nature (Silvestre *et al.*, 2011). The bio-nanocomposites packaging has great potential as an innovative food packaging technology to maintain the food quality and safety, and to extend the shelf life of the packaged food products. Although promising results were obtained, the road to the successful application of bionanocomposites in food packaging is still long. Considering the points above, this article is focused on the composition, preparation, characterization, and application of bio-nanocomposite materials in the food packaging area.

Composition of Bio-Nanocomposites

Bionanocomposites consist of a biopolymer having nanoparticles or nanofillers dispersed in the biopolymer matrix. These may be of different shapes (e.g., platelets, fibers, spheroids) or size, but at least one of the dimension must be in the range of 1–100 nm. The bio-nanocomposite systems require controlled mixing/compounding, stabilization of the achieved dispersion, the orientation of the dispersed phase, and the compounding strategies.

Biopolymers

Biopolymers are polymeric materials produced from renewable resources such as a plant, animal, and microorganisms. Biopolymers comprise monomeric units that are covalently bonded to form a larger assembly. There are three main classes of biopolymers, classified according to the monomeric units used and the structure of the biopolymer formed: polypeptides, which are short polymers of amino acids; polynucleotides (RNA and DNA), which are long polymers composed of nucleotide monomers; and polysaccharides, which are often linear bonded polymeric carbohydrate structure (Shankar *et al.*, 2016a; Shankar and Rhim, 2016a). Other examples of biopolymers include lignins, rubber, melanin, and suberin. Biopolymers can be categorized into three groups depending on the origin of the biopolymers, which includes natural biopolymers extracted from biomass (e.g., agro-resources), synthetic biopolymers from microbial production or fermentation (e.g., PHA), and synthetic biopolymers conventionally and chemically synthesized from biomass and petroleum products (e.g., PLA, PCL) (Fig. 2). Among the biopolymers, the most common type that has been studied to produce bio-nanocomposite materials for food packaging applications are carbohydrates, proteins, and their derivatives (Nafchi *et al.*, 2013; Shankar *et al.*, 2016b, 2017). Carbohydrate and protein-based polymers and their derivatives are commonly edible. Thus, they are safe as food packaging materials. Studies have shown that these polymers are degradable and could stimulate biodegradability of non-biodegradable materials when mixed them. However, biopolymer-based packaging films have poor mechanical properties which can be improved with additives such as plasticizers and nanofillers (Sorrentino *et al.*, 2007). Some biopolymers studied include cellulose such as cellulose acetate (Bruna *et al.*, 2014), carboxymethyl cellulose (Oun and Rhim, 2015), and hydroxypropyl methylcellulose (George *et al.*, 2014), chitosan (Shankar and Rhim, 2018b), agar (Orsuwan *et al.*, 2016; Shankar and Rhim, 2017; Shankar *et al.*, 2014a), gelatin (Kanmani and Rhim, 2014a; Shankar *et al.*, 2016c, 2014b), gluten (Rafieian *et al.*, 2014), alginate (Shankar *et al.*, 2018; Wang *et al.*, 2017), pectin (Shankar *et al.*, 2016b), synthetic biopolymers

Fig. 2 Classification of polymers based on their origin.

such as polylactide (PLA) (Arfat *et al.*, 2018; Rhim *et al.*, 2006), polyhydroxyalkanoates (Fabra *et al.*, 2016), poly(ϵ -caprolactone) (Yahiaoui *et al.*, 2015), and microbial synthesized polymers such as PBAT (Li *et al.*, 2015; Shankar and Rhim, 2018c). The most common synthetic biopolymer that has been studied is PLA which is produced from lactic acid. PLA can be generated by fermentation of carbohydrates from plant resources such as sugar beet and corn (Sorrentino *et al.*, 2007). The advantages of PLA include biodegradability, and the lifespan of PLA can be tailored accordingly. However, some of the drawbacks of using biopolymers as food packaging materials compared to the conventional non-biodegradable materials, especially those that are petroleum-derived include poor mechanical (e.g., low tensile strength) and barrier properties (e.g., high water vapor permeability). Biopolymers are brittle, have a low heat distortion temperature, and low resistance to prolonged process operations. For instance, the most favorable synthetic biopolymer, PLA, for food packaging exhibits low performance due to a low heat distortion temperature, low resistance to extreme heat and humidity, and low flexibility (Sorrentino *et al.*, 2007). Nevertheless, the advantages of using biopolymers as packaging materials, mainly to cater for societal demands for sustainability and environmental safety, have to lead to many studies directed towards improvement of biopolymers for food packaging applications. Incorporating nanofillers in the biopolymers have been established as a promising route to enhance mechanical and barrier properties of biopolymers.

Nanofillers

Many types of nanosized fillers (less than 100 nm) have been used to enhance the performance of biopolymers. The nanofillers that are commonly studied for food packaging applications can be classified into several types including nanoparticles, nanofibrils, nanocubes, nanoplates, nanorods, and nanotubes. The nanofillers can be basically divided into two major groups: (1) organic nanofillers and (2) inorganic nanofillers. Organic nanofillers include cellulose nanoparticles (Shankar and Rhim, 2016b), cellulose nanowhiskers (Wang *et al.*, 2017), cellulose nanofibrils (Oun and Rhim, 2017a), chitin nanofibrils (Shankar *et al.*, 2015a), chitin nanocrystals (Oun and Rhim, 2017b), starch nanocrystals (Dai *et al.*, 2015), melanin nanoparticles (Roy *et al.*, 2019), keratin nanoparticles (Spiridon *et al.*, 2013), lignin (Shankar *et al.*, 2015b; Shankar and Rhim, 2017), grapefruit seed extract (Shankar and Rhim, 2018c; Wang and Rhim, 2016) etc. Whereas, inorganic nanofillers include silver nanoparticles (Kanmani and Rhim, 2014a; Roy *et al.*, 2019), gold nanoparticles (Shankar *et al.*, 2016c), zinc oxide nanoparticles (Shankar *et al.*, 2014b), copper oxide nanoparticles (Shankar *et al.*, 2014a, 2017), titanium oxide nanoparticles (Zhang *et al.*, 2017), sulfur nanoparticles (Shankar and Rhim, 2018b), graphene oxide nanoparticles (Arfat *et al.*, 2018) etc. Another type of nanofillers includes organic-inorganic hybrid nanofillers (Guo *et al.*, 2016; Oun and Rhim, 2017c) and inorganic-inorganic hybrid nanofillers (Shankar *et al.*, 2016c). Researchers have used different types of fillers and biopolymers to produce bio-nanocomposite materials, and have studied different properties of the resulting bio-nanocomposite materials, making a comparison based on the published literature difficult. For example, (Shankar *et al.*, 2014b) studied the physiochemical properties of antimicrobial composite films made from gelatin and different types of zinc oxide nanoparticles). Rafieian *et al.* (2014) studied the thermomechanical and morphological properties of bio-nanocomposite films made from wheat gluten matrix and cellulose nanofibrils, while Arfat *et al.* (2017) studied the thermo-mechanical, rheological, structural, and

Fig. 3 Various types of nanofillers.

antimicrobial properties of fish skin gelatin films incorporated with silver-copper nanoparticles. Fig. 3 represents some of the nanofillers that can be used for the preparation of nanocomposite films.

Types of Bio-Nanocomposites

The commercial use of biopolymers-based composite films for food packaging is currently limited due to the problems in their performance, processing, and cost (Zhang *et al.*, 2014). At this point, nanotechnological approaches have opened new ways for the utilization of great performance, reduced weight, green nanocomposite materials making them supplant traditional non-biodegradable petroleum-based plastic packaging materials. The inclusion of nanoparticles in biopolymers can enhance their mechanical and barrier properties which are associated with high aspect ratio and high surface area of the nanoparticles (Rhim *et al.*, 2013).

Carbohydrate-Based Bio-Nanocomposites

Agar

Agar is one of the most favorable polysaccharides for developing biodegradable films due to its moderate water resistant property and high mechanical strength (Giménez *et al.*, 2013). Agar is a mixture of agarpectin and agarose, in which the former is a slightly branched and sulfated nongelling polymer and the later is a linear gelling polymer composed of a repeating unit of agarobiose (composed of 1,3-linked-D-galactose and 1,4-linked 3,6-anhydro-L-galactose). Since the most agarpectin fraction is removed during processing, food-grade agar is mainly composed of agarose with a molecular weight of about 120 kDa (Shankar *et al.*, 2014a). Agar has been successfully used to make nanocomposites with cellulose, clay, copper, and silver, nanoparticles and reported that the mechanical properties and water vapor permeability have been improved with the addition of nanofillers (Giménez *et al.*, 2013; Kanmani and Rhim, 2014b; Orsuwan *et al.*, 2016; Shankar *et al.*, 2015b, 2017, 2014a).

Alginate

Alginate is a naturally occurring poly-anionic polysaccharide derived from brown marine algae (Phaeophyceae), and it is commercially extracted from brown seaweed including giant kelp (*Macrocystis pyrifera*, *Ascophyllum nodosum*) and various types of Laminaria species such as *Laminaria hyperborea*, *Laminaria digitata*, and *Laminaria japonica* (Lee and Mooney, 2012). Alginate is made up of a linear block co-polymer of 1, 4-linked β -D-mannuronic and α -L-guluronic residues in varying proportions. As a low-cost, abundantly available, biocompatible and environmentally friendly biopolymer, it has been used in numerous applications in the food and biotechnology industries such as a non-toxic food additive, thickening and gelling agent, and colloidal stabilizer (Carneiro-da-Cunha *et al.*, 2010). Alginate films are highly transparent with high mechanical strength. However, they have a poor water vapor barrier property with low flexibility like other biopolymer-based films. Various types of alginate based nanocomposite films have been prepared using different types of nanofillers such as nanocellulose (Wang *et al.*, 2017), copper oxide nanoparticles (Shankar *et al.*, 2017), zinc oxide nanoparticles (Kanmani and Rhim, 2014b), halloysites (Shankar *et al.*, 2018).

Pectin

Owing to the environmentally friendly nature, good processing ability, and acceptable mechanical and barrier properties, pectin has been used for food packaging and other value-added applications. Pectin is an important component of the cell walls of terrestrial plants that widely used as a functional food ingredient, and about 4–5 g of pectin is consumed daily in the diet (Willats *et al.*, 2006). Pectin is a family of polysaccharides and oligosaccharides with diverse structures (Ridley *et al.*, 2001). Since pectin is rich in galacturonic acid (GalA), the FAO and EU stipulated that pectin must contain at least 65% of GalA. Pectin can form a gel when homogalacturonan is crosslinked to form a three-dimensional crystalline network in which water and solutes are trapped. Gelling properties of pectin are determined by various factors such as the type of pectin, the degree of methyl esterification, the degree of acetylation, temperature, pH, sugar and, calcium (Willats *et al.*, 2006). Various nanofillers have been used to improve the mechanical and functional properties of the pectin-based composite films. Shankar *et al.* (2016b) prepared pectin-based composite films incorporated with *Caesalpinia mimosoides* Lamk extract capped silver nanoparticles. The UV-light barrier, thermal stability, mechanical strength, and water vapor barrier properties of the pectin films significantly increased after incorporation of AgNPs. Also, the pectin/AgNPs nanocomposite films showed strong antibacterial activity against *Escherichia coli* and *Listeria monocytogenes*.

Carrageenan

Carrageenan is a water-soluble sulfated polysaccharide extracted from various species of *Rhodophyta* (red marine algae) and consists of long linear chains of D-galactose and D-anhydrogalactose with anionic sulfate groups (OSO_3^-) (Liu *et al.*, 2015). The excellent film-forming ability of carrageenan promoted its use for the preparation of composite films using carrageenan alone or combined with other biopolymers. Various nanofillers have been used as a reinforcing material to improve the mechanical and functional properties of carrageenan-based nanocomposite films. Shankar *et al.* (2015a) prepared carrageenan-based nanocomposite films reinforced with chitin nanofibrils. The found that the carrageenan/chitin nanofibrils composite films were

smooth and flexible and the chitin nanofibrils were dispersed uniformly in the carrageenan polymer matrix. The tensile strength and modulus of carrageenan film were increased significantly ($p < 0.05$) after chitin nanofibrils reinforcement with up to 5 wt%.

Cellulose

Cellulose nanostructures have been most usually applied as reinforcing phases, but they may also be used as matrices for a variety of materials including films for food packaging applications. Chitosan nanoparticles were incorporated into cellulose films, in which 5% addition of chitosan nanoparticles into cellulose films resulted in 85% inhibition in *Escherichia coli*. Cross-linking of the cellulose films with citric acid reduced water absorbency by 50% the growth of *E. coli* by 3% (Romainor *et al.*, 2014). Ghule *et al.* (2006) proposed a simple approach to produce a nanoparticle-coated antimicrobial paper. They used an ultrasound-assisted approach to coat the cellulose fibers over the paper surface with zinc oxide nanoparticles. The coated paper showed antimicrobial activity against *E. coli* 11,634 (Ghule *et al.*, 2006). A similar study investigated the antimicrobial effect of copper nanoparticles incorporated into chemically modified cotton cellulose fibers (Mary *et al.*, 2009). Siqueira *et al.* (2014) analyzed the antimicrobial effect of silver (Ag) nanoparticles incorporated into carboxymethylcellulose (CMC) films. The Ag-CMC nanocomposite inhibited the growth of a Gram-positive bacteria, *Enterococcus faecalis*, and a Gram-negative bacteria, *E. coli*, at a concentration of 0.1 $\mu\text{g/mL}$ (Siqueira *et al.*, 2014).

Chitosan

Chitosan is a random copolymer obtained from the alkaline deacetylation of chitin, formed by D-glucosamine and N-acetyl-D-glucosamine units, linked by β -1,4-glycosidic linkages. The ratio between the two units is considered as the degree of deacetylation (Bedian *et al.*, 2017; Verlee *et al.*, 2017). When the deacetylation degree of CS reaches about 50%, it becomes soluble in aqueous acidic media (Chang *et al.*, 1997). When chitosan is dissolved in an acidic environment, the amino groups in the chain protonate and the polymer becomes cationic, allowing it to interact with diverse types of molecules, thus turning chitosan into the only cationic marine polysaccharide (Lizardi-Mendoza *et al.*, 2016). This positive charge is thought to be responsible for its antimicrobial activity, via the interaction with the negatively charged cell membranes of microorganisms (Cazón *et al.*, 2017). Chitosan has been extensively studied due to its excellent film formability, antibacterial properties, physical and mechanical properties, biocompatibility and biodegradability (Khokhlova *et al.*, 2012; Munteanu *et al.*, 2014). Chitosan is obtained by alkaline deacetylation of chitin, which is extracted from a variety of crustacean shells, fungal cell walls and other biological materials (Kim *et al.*, 2011). Chitosan, which listed in the generally recognized as safe (GRAS) materials by U.S. Food and Drug Administration in 2001, is used as a food preservative since it is biocompatible and non-toxic for human beings and animals (Friedman and Juneja, 2010). In food industries, chitosan has been used extensively for surface coating of meat and fruit products to reduce food deterioration and water loss, as well as a delay in the ripening of fruits (Aranaz *et al.*, 2009). Chitosan is also known to have antimicrobial activity that inhibits the growth of a wide range of fungi, pathogenic bacteria and spoilage microorganisms (Dutta *et al.*, 2009). Shankar and Rhim (2018b) prepared chitosan-based nanocomposite films reinforced with sulfur nanoparticles and obtained improved properties of nanocomposite films with strong antibacterial activity against *E. coli* and *L. monocytogenes*.

Starch

Oleyaei *et al.* (2016) also used a solvent casting method to prepare ternary potato starch bio-nanocomposite films containing sodium montmorillonite (MMT) and TiO_2 nanoparticles. A 5% MMT addition to starch-based bio-nanocomposite showed a 50% reduction in water vapor permeability. Moreover, those blend nanocomposite films showed an antimicrobial activity against *Listeria monocytogenes* which is a Gram-positive bacterium (Oleyaei *et al.*, 2016). Nearly the same enhancement in water vapor barrier properties and tensile strength was reported with starch-based nanocomposite film incorporated with hydrothermally synthesized zinc oxide nanoparticles (Andiyana and Suyatma, 2016).

Gellan and guar-gum

Gellan is released and extracted from the bacterium *Sphingomonas elodea* (previously named *Pseudomonas elodea*). Gellan gum is a linear anionic heteropolysaccharide having a tetrasaccharide repeating unit comprising of rhamnose, D-glucose and D-glucuronic acid in the ratio of 1:2:1. It has the potential for partial or entire replacement of existent gelling agents (Chaudhary *et al.*, 2013). Mun *et al.* (2015) reported the preparation and characterization of graphene oxide-gellan gum-sodium alginate nanocomposites. The obtained findings revealed that the addition of graphene oxide and sodium alginate drastically improved the tensile strength and Young's modulus of gellan gum. Arfat *et al.* (2017) investigated the potential of guar gum-based nanocomposite films prepared by incorporating silver-copper alloy nanoparticles (Ag-Cu NPs) through solution casting method as an active food packaging material. Tensile test results showed an improvement in mechanical strength. Also, the films showed excellent UV light and oxygen barrier capability. Furthermore, strong antibacterial activity was observed against both Gram-positive and Gram-negative bacteria (Arfat *et al.*, 2017).

Others

Rhim and Wang (2013) prepared a ternary blend bio-hydrogel film by solvent casting method comprised of agar, konjac glucomannan powder, and κ -carrageenan reinforced with nanoclay (Cloisite® 30B). They found that the addition of nanoclay improved the tensile strength of the ternary blend bio-hydrogel film from 62 to 76 MPa and decreased the water vapor

permeability from 1.25×10^{-9} to 1.05×10^{-9} g m⁻¹ s⁻¹ Pa⁻¹. The ternary blend bio-hydrogel films exhibited an enormous increase in the water holding capacity up to 5488%. They applied the developed film for the packaging of green onion and found the potent application of the developed film for the antifog packaging of highly respiring fresh produce like spinach (Rhim and Wang, 2013).

Protein-Based Bio-Nanocomposite

In commercial applications, the following animal-derived proteins used are: casein, whey protein, collagen, egg white and fish myofibrillar protein. The plant-based proteins also under large scale application consideration include soybean protein, zein (corn protein) and wheat gluten. Compared with non-ionic polysaccharide films, protein films, due to their more polar nature and more linear (non-ring) structure and lower free volume offer better oxygen barrier properties and lower water vapor permeability (Arora and Padua, 2010). The transparent films based on whey protein show good oxygen barrier and TiO₂ or ZnO were added to form nanocomposites with improved antimicrobial properties used to fabricate food-grade, biodegradable packaging materials (Sothornvit and Krochta, 2005; Zhou *et al.*, 2009; Shi *et al.*, 2008). Chen and Zhang (2006) and Yu *et al.* (2007) showed that the addition of small amounts (<1 wt%) of TiO₂ nanoparticles significantly increased the tensile properties of whey protein film (from 1.69 to 2.38 MPa). Soy protein nanocomposite films exhibited reduced water vapor permeability, improved elastic modulus and tensile strength compared with the neat polymer. Zein, a biodegradable polymer, is used in the food industry as a coating agent (Liu *et al.*, 2005). It is less water sensitive than other biopolymers but shows high water vapor permeability and low tensile strength when compared with commodity polymers. To ameliorate its inherent brittleness, plasticizers may be used.

Gelatin

Gelatin is a water-soluble protein derived from the partial hydrolysis of the fibrous insoluble protein, collagen. Collagen is a major protein constituent in the bones, cartilages, and skins of animals and fish. Therefore, the properties of the gelatin are greatly influenced by the source, age of the animal, type of collagen, and processing method (Gómez-Guillén *et al.*, 2011). For the production of gelatin, various mammalian sources are used, such as pig skin (46%), bovine hide (29.4%), and pork and cattle bones (23.1%). Nonmammalian sources like fish skin (1.5%) are not significant, but have recently gained momentum as potential alternatives (Gómez-Guillén *et al.*, 2011). However, the rheological properties of gelatin obtained from nonmammalian sources are less stable than those of mammalian sources. Depending on the processing methods, gelatin is classified into two types, i.e., type A gelatin and type B gelatin (Arvanitoyannis, 2002). Type A gelatin is obtained by acid treatment of collagen and it has an isoelectric point of 7–9. However type B gelatin is derived from the alkali treatment of collagen with an isoelectric point of 4–5 (Gómez-Guillén *et al.*, 2011). Initially, the insoluble native collagen is pretreated by heating above 45°C in water to get the soluble gelatin from collagen. Then, the chemical treatment breaks the noncovalent bonds and disrupts three-dimensional structures of the proteins, thus resulting in adequate swelling and solubilization of collagen. The subsequent heat treatment cleaves the hydrogen and covalent bonds and unfolds the triple-helix, resulting in helix-to-coil transition and conversion of collagen to soluble gelatin. The degree of collagen conversion into gelatin is dependent on the pretreatment with warm-water extraction, pH, temperature, and extraction time (Hanani *et al.*, 2014). Gelatin is composed of 50.5% carbon, 25.2% oxygen, 17% nitrogen, and 6.8% hydrogen (Smith, 1921). Gelatin is a mixture of α -chains (one polymer/single chain), β -chains (two α -chains covalently cross-linked), and γ -chains (three α -chains covalently cross-linked) (Papon *et al.*, 2007). Generally, gelatin with a high percentage of α -chain possesses higher gel strength. The amino acid composition of gelatin is characterized by the structure of Ala-Gly-Pro-Arg-Gy-Glu4Hyp-Gly-Pro- (Shankar *et al.*, 2010; Nilesh *et al.*, 2011). Gelatin is a tasteless, odorless substance and is produced in a granulated or powdered form. Gelatin is hygroscopic, but its water absorbing capacity depends on the relative humidity at which it is dried and stored. Extreme pH and high temperature denature the gelatin and change its properties by disrupting three-dimensional structures of gelatin and forming a random coil. Therefore, the processing conditions of gelatin need to be carefully controlled to get a high gelling strength. By exploiting its diverse functional properties, gelatin has been widely used industrially, not only for food packaging materials, but also in various applications such as emulsifiers, cosmetics, photography, foaming agents, hydrogels, and colloid stabilizers (Arora and Padua, 2010; Shankar *et al.*, 2010). In the pharmaceutical industry, gelatin has been exploited for making hard and soft capsules, emulsions, ointments, plasma expanders, and wound dressing materials (Ulubayram *et al.*, 2001; Wang *et al.*, 2012a,b). In the food industry, gelatin is used in food packaging and food coating materials, and also as gelling, stabilization, texturization, and emulsification for bakery, beverages, confectionery, and dairy products (Djagny *et al.*, 2001). Gelatin is a promising protein biopolymer, owing to its remarkable film forming property, biodegradability, abundance, and cost-effectiveness (Farris *et al.*, 2011). Also, the introduction of nanoparticles into gelatin matrices greatly enhances the overall properties, such as the biocompatibility, physical and mechanical properties, and biodegradability of gelatin-nanocomposite films (Duncan, 2011). Also, some of the nanocomposite systems provide extra-functional properties, such as antioxidant and antimicrobial functions. Bionanocomposite films that are fortified with antimicrobial properties especially broaden the application range of the films in food packaging industries. They mitigate the risk of foodborne pathogens outbreak, which subsequently renders supreme food safety and quality, and extends the shelf life of food (Llorens *et al.*, 2012). Numerous metallic or inorganic nanoparticles such as gold, silver, zinc, copper, and clay, in conjunction with gelatin, have been used to improve the functional properties of gelatin. Additionally, gelatin has been used for the preparation of completely biodegradable

bionanocomposite food packaging films. This is done by blending with other organic polymers, such as nanocrystals of cellulose, starch, chitin, and chitosan (Pereda *et al.*, 2011).

Soy protein

Soy protein has attracted great research interest for the development of environmentally friendly protein materials with potentially good properties, such as regeneration, biocompatibility, biodegradability, etc., (Echeverría *et al.*, 2014; Garrido *et al.*, 2013). Soy protein has been widely used in hydrogels, adhesives, plastics, films, coatings and emulsifiers, and it has also been reported as a promising material for biotechnological and biomedical utilization (Zhao *et al.*, 2013). Soy protein is extracted from soybean seeds that are used to obtain soy oil and can be used for food packaging or edible films since it meets food grade standards (Garrido *et al.*, 2013). Soy proteins are composed of a mixture of albumins and globulins, 90% of which are storage proteins with globular structure, consisting mainly in 7S (β -conglycinin) and 11S (glycinin) globulins (Ciannamea *et al.*, 2014; Koshy *et al.*, 2015). Soy protein is commercially available in three different forms from soybean processing plants, namely, soy flour (SF: 54% protein), soy protein concentrate (SPC: 65%–72% protein) and Soy protein isolate (SPI: $\geq 90\%$ protein) (Saenghirunwattana *et al.*, 2014). Soy flour is made by grinding soybeans into a fine powder, which contains about 56% protein and about 34% carbohydrates. Soy protein concentrate, prepared by eluting soluble components from defatted soy flour, contains more than 65% protein and 18% carbohydrates. Soy protein isolate is a highly refined or purified form of soy protein with a minimum protein content of 90% on a moisture-free basis. It is made from defatted soy flour which has had most of the nonprotein components, fats and carbohydrates removed (Kalman, 2014). The protein content of soy protein isolate (SPI) is more than those of other soy protein products, which makes it exhibit a higher film-forming ability. Moreover, SPI also produces softer, more transparent and flexible films compared to those derived from other sources, and they have effective gas barrier properties compared to films prepared from lipids and polysaccharides (Gonzalez and Alvarez Igarzabal, 2014). SPI films do not show satisfactory mechanical properties or water vapor barrier properties in practical applications due to their inherent hydrophilicity. SPI contains 58% polar amino acids that cause hydrophilicity as well as the strong molecular interaction of natural protein; and these properties become poorer under highly humid conditions (Choi *et al.*, 2003). Various methods to enhance the physical properties of protein films have been suggested. Environmental friendly thermoplastic nanocomposites were successfully developed using a colloidal suspension of chitin whiskers (wet basis) as a filler to reinforce SPI plastics by Lu *et al.* (2004). Analysis showed that nanocomposites with lower whisker content exhibit a relatively uniform dispersion in the SPI matrix than those with higher chitin content. Compared to glycerol plasticized SPI sheet, the chitin filled SPI composites exhibited an increase in Young's modulus and tensile strength from 26 to 158 MPa and 3.3–8.4 MPa, with increasing chitin content from 0 to 20 wt%. Wang *et al.* (2006) prepared SPI/cellulose whisker composites using a colloidal suspension of cellulose whiskers from cotton linter pulp and reinforced to SPI polymer matrix. With the addition of 0–30 wt% (wet basis) of cellulose whiskers, strong interactions occurred between the cellulose whiskers and the SPI matrix that resulted in improved mechanical and barrier properties of the nanocomposite films. Also, the inclusion of inorganic nano fillers into the soy protein matrix results in a drastic change in matrix properties which depends on many factors such as nanoparticle size, aspect ratio, surface area, and polymer/filler compatibility. SPI-MMT polymer clay nanocomposites have been prepared using several methods like melt extrusion (Kumar *et al.*, 2010), casting (Echeverría *et al.*, 2014) and solution intercalation (Chen and Zhang, 2006). The nanoclay was shown to become highly exfoliated with positive surface charges on the globulins anchoring into the negatively charged montmorillonite galleries, and good nanoclay dispersion occurred due to electrostatic interactions and hydrogen bonding. Zhao *et al.* (2013) prepared SPI/AgNPs films, that showed considerable antimicrobial activity against both Gram-positive bacteria (*Staphylococcus aureus*) and Gram-negative bacteria (*E. coli*) even when the Ag content was only 0.1%. When the Ag content in the film was larger than 0.5% (w/w), almost all of the bacteria were killed within 2 h. Therefore, the addition of AgNPs was found to have the effect to prevent bacteria growth on the SPI based materials, and thus prolong their useful life. SPI (5.0 g/100 mL) films embedded with nano-TiO₂ (0, 0.5, 1.0, 1.5 and 2.0 g/100 mL) were prepared by solution casting (Wang *et al.*, 2012a,b) and modified by ultrasonic/microwave assisted treatment (UMAT) by Wang *et al.* (2014). Nano-TiO₂ could react with SPI, and these interactions can result in stronger interfacial adhesion between nano-TiO₂ and SPI matrix, which leads to a higher efficiency of the stress transfer from the matrix to the nanoparticles and hence an increase in tensile strength.

Application of Bio-Nanocomposites

Bio-nanocomposite films are used for a variety of active packaging and smart packaging applications, as well as for improving film properties and application of biodegradable packaging materials (Fig. 4).

Antimicrobial Packaging

One of the main reasons for the deterioration of food quality is microbial growth, which leads to discoloration, off-flavor development, textural changes, and the loss of nutritive value, and thus reduces the shelf-life of foods and increases the risk of food-borne illness (Malhotra *et al.*, 2015). Antimicrobial packaging prolongs the lag time of microbial growth and slows the growth rate of microorganisms, extending the shelf life of the food and maintaining the quality and safety of the food (Han, 2000). The antimicrobial packaging film can be brought into direct contact with the food surface to evaporate the antimicrobial agent or deliver it to the food. Many antimicrobial agents such as ethanol, carbon dioxide, silver ions, chlorine dioxide,

Fig. 4 Multifunctional applications of bio-nanocomposite packaging films.

antibiotics, bacteriocins, organic acids, essential oils, and spices have been tested to inhibit the growth of microorganisms in packaged foods (Jayasena and Jo, 2013; Malhotra *et al.*, 2015), but antimicrobial packaging is commercially limited except silver nanomaterials (Realini and Marcos, 2014). Although an increasing effort has recently been devoted to the development of antimicrobial packaging solutions, there are considerable differences in the ways antimicrobials are used at laboratory-scale and in real-time applications, and, together with regulatory issues and technical constraints, these differences are some of the main factors limiting the commercialization of antimicrobial packaging systems (Realini and Marcos, 2014; Malhotra *et al.*, 2015). To successfully introduce antimicrobial packaging into the market, it is essential to choose a package that is compatible with antimicrobial agents and the environmental conditions facing the particular food. A multidisciplinary approach involving researchers from all fields of biotechnology, particularly microbiology, food technology, engineering, and materials science, will be necessary to create antimicrobials with a promising future in the food packaging industry (Malhotra *et al.*, 2015). Several types of antimicrobial packaging have been commercialized (Ahmed *et al.*, 2017; Fang *et al.*, 2017).

Antioxidant Packaging

High levels of oxygen in food packages can facilitate microbial growth (such as aerobic bacteria, molds, and insects), oxidation of lipids and pigments, and loss of O₂-sensitive nutrients such as vitamins A, C, and E, which lead to changes in flavor (typical of rancidity), color, texture, and nutritive value. These changes can render the product unacceptable for human consumption and may even result in the formation of toxic aldehydes due to the degradation of polyunsaturated fatty acids that have been positively correlated with the prevention of cardiovascular disease (Fang *et al.*, 2017; Realini and Marcos, 2014). Additionally, oxygen has a considerable effect on the respiration rate and ethylene production rate of respiring foodstuffs such as fruits and vegetables (Lopez Rubio *et al.*, 2004). Therefore, the removal of O₂ from the package headspace is crucial to improving the quality and safety of oxygen-sensitive food products, and it has long been a goal of food-packaging scientists. Although vacuum packaging combined with a good oxygen barrier in the packaging film can effectively limit the presence of oxygen, such techniques do not completely remove the oxygen inside the package because O₂ permeates from the exterior through the packaging film, because of residual O₂ at the time of packing, or because of poor sealing (Ahmed *et al.*, 2017). Antioxidants can be directly added to food formulations by using certain processing steps such as spraying, immersion, or mixing, which may cause changes in food quality parameters (color or taste) and may affect consumer acceptance of the product.

Furthermore, such methods may encounter the following limitation: once the active compounds are consumed in the reaction, the protection ceases, and the quality of the food degrades more quickly (Mastromatteo *et al.*, 2010). In these cases, active antioxidant packaging represents an innovative strategy to improve the stability of oxidation-sensitive food products and thus extend their shelf-life by incorporating antioxidant agents in a polymer. Table 1 represents the application of nanocomposites in the packaging of food.

Biodegradability, Renewability, and Sustainability

Biodegradation means fragmentation, loss of mechanical properties or chemical modifications through the action of microorganisms when polymeric materials are exposed to a natural environment (Calmon-Decriaud *et al.*, 1998). Biodegradation is a complex process that finally converts the material into carbon dioxide, water, inorganic compounds, methane and biomass (Lucas *et al.*, 2008). Environmental conditions such as atmospheric pollutants, climate, and humidity, as well as the properties and composition of polymeric materials, are some of the reasons that may interfere on their biodegradability (Lucas *et al.*, 2008).

Table 1 Application of packaging materials

Function	Biopolymer	Nanofiller	Application	Reference
Antimicrobial	Chitosan	ZnO NPs, neem oil	Carrot	Sanuja <i>et al.</i> (2015)
	Gelatin	ZnO nanorods/clove essential oil	Shrimp	Ejaz <i>et al.</i> (2018)
	Cellulose	AgNPs	Fresh-cut melon	Fernandez <i>et al.</i> (2010)
	Pullulan	AgNPs	Turkey deli meat	Khalaf <i>et al.</i> (2013)
	Pullulan	ZnO NPs, essential oils	Meat and poultry products	Morsy <i>et al.</i> (2014)
	Agar	Ag-MMT NPs	Fior di Latte cheese	Incoronato <i>et al.</i> (2011)
	Gelatin	Oregano, rosemary essential oils	Cod smoke sardine	Gomez-Estaca <i>et al.</i> (2007)
	Gelatin	Laurel essential oil	Rainbow trout fillets	Alparslan <i>et al.</i> (2014)
	Chitosan	Grapefruit seed extract	Sliced bread	Tan <i>et al.</i> (2014)
	CMC-Chitosan	ZnO NPs	Bread	Noshirvani <i>et al.</i> (2017)
	Starch	Green tea extract	Beef	Nisa <i>et al.</i> (2015)
	Grain protein	Green, black and oolong tea extracts	Fresh pork	Yang <i>et al.</i> (2016)
	Whey protein	Cinnamon (85%) + Rosemary essential oil (15%)	Pork salami	Ribeiro-Santos <i>et al.</i> (2018)
Antioxidant	Whey protein	Oregano extract	Painho	Catarino <i>et al.</i> (2017)
	Chitosan	Tea polyphenols	Cooked pork sausages	Qin <i>et al.</i> (2013)
	Chitosan	MMT, rosemary and ginger essential oil	Fresh poultry meat	Pires <i>et al.</i> (2018)
	Chitosan	TiO ₂	Tomato	Kaewklin <i>et al.</i> (2018)
	Chitosan			
Ethylene absorber	Chitosan			

Among abiotic conditions, eg: light, mechanical, thermal, and chemical effects also provoke deterioration that deteriorates the polymeric structure preferring the biodegradation process (Eubeler *et al.*, 2010; Shah *et al.*, 2008). Biodegradation of polymer matrices depends mainly on the length of the polymer chain, the complexity of the polymer matrix, and their degree of crystallinity (Pantani and Sorrentino, 2013). Polymer products degrade in a controlled way, such as natural polymers (humus, lignin, rubber) and synthetic polymers (polyolefins) follow the mechanism of oxo-biodegradation (Rydz *et al.*, 2014). During the degradation of oxocarboxylic acid molecules, low molecular weight alcohols, aldehydes, and ketones produced by peroxidation process that is initiated by heat or light, which are the main cause of the loss of mechanical properties of the polymers, followed by bio-assimilation by bacteria, fungi, enzymes resulting in increasing biomass and CO₂. Hydrobiodegradation is a process that yields biodegradable products from cellulose, starch, and polyesters. The aliphatic polyesters are hydrolyzed rapidly in an aqueous medium and biodegrade (Scott and Wiles, 2001). However, cellulose and starch swell in water and then biodegrade. There are hydro-biodegradable aliphatic polyesters such as polylactic acid and poly (hydroxy acid).

The biodegradable polymers must disintegrate in a short time and must be compatible with the composting process. They should not release toxic substances during degradation while maintaining the quality of the compost produced (Scott and Wiles, 2001). Absorption and interaction between the polymers and chemicals may affect the properties of the polymer being investigated. Therefore, it is necessary to evaluate the effectiveness and suitability of biopolymers for storage and food packaging as well as their byproducts during biodegradation.

Future Perspectives and Conclusion

Bionanocomposites represent an inspiring route for creating new and innovative packaging materials. By adding appropriate nanoparticles such as organic, inorganic or organic-inorganic hybrid nanomaterials, it will be probable for fabricating films for packaging have good mechanical, barrier thermal and other functional properties. They can reduce flammability significantly and maintain the transparency of the polymer matrix. Inserted nanomaterials into packaging materials as nano-sensors will alert the customer if food has gone bad. Bionanocomposites are a viable technology for “new” materials for near-future packaging applications, especially for flexible, fire resistance, antimicrobial and transparent barrier packaging films.

In conclusion, the area of bio-nanocomposites as packaging materials still need scientific research and improvement to develop the shelf life, quality and marketability of diverse packaging materials. What can be in the near, design and incorporate multiple desired functionalities? For example antimicrobial, antibiotic, biodegradable, and combine responses to environmental or chemical changes. Moreover, it can be in the not-so-near future, fabricate bioinspired nanostructure polymers nanocomposites. Look at nature’s examples of packaging, skins, structures with specific processes, and imagine if we could make synthetic equivalents.

Introduction

Cellulose is one of the most abundant natural polymers on the planet earth and renewed continuously through photosynthesis. Building block derived from the renewable resources attracts considerable attention for the design of novel materials and systems. Cellulosic nanomaterials can be regarded as sustainable nano sized materials due to easy availability of source raw materials, renewability, nontoxicity, biodegradability etc. There is a rapid growing trend for the use of nanocellulose as a potential renewable nanomaterial for the development of novel functional materials (Yanamala *et al.*, 2014). Like other types of cellulosic nanomaterials, cellulose nanocrystals (CNC) are nontoxic, sustainable and renewable nanomaterials with high surface area, low density and excellent mechanical properties. Therefore, CNC have emerged as promising green nanofillers for the reinforcement in the range of polymer matrix and improve the properties of nanocomposites (Shin *et al.*, 2017; Mannan *et al.*, 2016).

Composite or nanocomposites are multi-phase materials manufactured by combination of various component materials in order to achieve the functional properties that none of the individual components possesses. In the composite/nanocomposite materials various phases retain their physical identity while bonded together by physical/chemical or combination of physical and chemical means. In a polymer based nanocomposite, polymer is a major phase while nanofillers are minor or reinforcement phase. Some of the well-known nano-reinforcements are nano-titanium dioxide (Anh *et al.*, 2018; Huppmann *et al.*, 2014), silica nanoparticles (Abdollahi *et al.*, 2015; Kang *et al.*, 2018; Tang *et al.*, 2016; Krishnan *et al.*, 2011), nano-clay (Dabbaghianamiri *et al.*, 2017; Zhai *et al.*, 2017; Zhou *et al.*, 2016), various carbon based nano-reinforcement (viz. carbon nanotube (Kausar *et al.*, 2017; Sapalidis *et al.*, 2018), graphene (Ma *et al.*, 2018; Sobolewski *et al.*, 2016; Zhang *et al.*, 2018), carbon nanofiber (Bafekrpour *et al.*, 2013) etc.), cellulose nanocrystal (El Miri *et al.*, 2015; Liu *et al.*, 2015; Vestena *et al.*, 2016) etc. Cellulose nanocrystal is renewable nano reinforcing material and can be used for the fabrication of high performance nanobiocomposites.

Most of the synthetic polymers derived from the petroleum based raw materials are non-degradable in nature. Environmental pollution by nondegradable synthetic polymers is a serious concern now a days, and researchers are looking for completely degradable or partially degradable polymeric products for daily uses. The major concern with the synthetic polymers derived from the petroleum based resource is the disposal as the solid waste disposal continues to be an ever increasing concern in this planet. As the landfills continue to be filled up by the synthetic polymers, there has been a significant demand for the renewable materials or nano-materials based polymer products (Tsai and Wertheim, 2001). Biodegradability of synthetic polymer is an interesting field of research to create polymeric products in order to decompose it into harmless byproducts when discarded. The demand for environmental friendly nano-materials which can be incorporated into the polymer matrix to enhance the degradability will increase (Doke and Garag, 2003). Therefore, the aim of this book article is to provide an overview of cellulose nanocrystal as a prospective renewable nanoreinforcement in the synthetic polymers to enhance the degradability of non-degradable synthetic polymers.

Cellulosic Nanomaterials

Cellulosic nanomaterials are group of renewable nanomaterials of cellulose structure with at least one dimension is less than 100 nm. Various types of cellulosic nanomaterials includes cellulosic nanofibrils, cellulosic nanocrystal and bacterial synthesized nanocellulose (Aitomaki and Oksman, 2014). Bacterial nanocellulose is produced by selective bacteria e.g., *Gluconacetobacter xylinum* (Avila *et al.*, 2014; Kuzmenko *et al.*, 2013). In a controlled environment, selective bacteria produces 3D network of nanofibrils which represents an interesting nano biomaterials for various biomedical applications such as artificial skin, artificial blood vessel, wound dressing, carrier for drug delivery etc (Barud *et al.*, 2016). Cellulosic nanomaterials can be prepared by bottom up and top down approaches. Preparation of cellulose nanofibrils from lignocellulosic biomass by using mechanical method, and preparation of cellulose nanocrystal from lignocellulosic biomass by dissolving amorphous region are top down approaches of nano-cellulose preparation. While, bacterial synthesis of nano-cellulose in a controlled environment is a typical example of bottom up approach for nano-cellulose preparation. Abraham *et al.* (2011) reported a novel process of acid hydrolysis followed by steam explosion for preparation of stable colloid suspension of cellulose nanofibrils (CNF) by using various lignocellulosic raw materials such as banana (pseudo stem), jute (stem) and pineapple leaf fiber. Steam explosion further remove amorphous region of lignin, hemicellulose etc. from inner part of fibers by depolymerization and defibrillation. Steam explosion i.e., high pressure steaming followed by decompression is an effective method for separation of nanofibrils from biomass (Cherian *et al.*, 2010, 2008). Diameter of cellulose nanofibrils is 5–50 nm for the pineapple raw fibers and 15–25 nm when nanofibrils extracted from

the jute ([Fig. 1](#); [Abraham *et al.*, 2011](#)). Cellulose nanofibrils can also be prepared by high pressure homogenizer. [Chun *et al.* \(2012\)](#) reported diameter of CNF from 20 to 50 nm, after 12 passes through high pressure homogeneizer ([Fig. 2](#)). Another form of cellulosic nanomaterial i.e., cellulosic nanocrystal can be prepared by selectively hydrolysis of amorphous region from raw cellulose.

Preparation of Cellulose Nanocrystal

Cellulose nanocrystal can be prepared by following various top down methods. Some of the extracted cellulose nanocrystals from various cellulosic resources with their dimensions are tabulated in [Table 1](#) ([Tabassi *et al.*, 2016](#); [Dhar *et al.*, 2015a](#); [Urena-Benavides](#)

Table 1 Characteristics of cellulose nanocrystals

Source raw material	Process	Dimension of CNC (nm)		Ref.
		Lowest dimension	Length	
Microcrystalline cellulose (MCC)	Acid hydrolysis	61	272	(Tabassi <i>et al.</i> , 2016)
Bamboo (Bambusa balcooa)	Acid hydrolysis	15–20	400–600	(Dhar <i>et al.</i> , 2015a)
Cotton	Sulphuric acid hydrolysis	6.8	130	(Urena-Benavides and Kitchens, 2012)
Microcrystalline cellulose	Sulphuric acid hydrolysis	6.96 ± 0.87	178 ± 55	(Cho and Park, 2011)
Leaves <i>licuri</i>	Sulphuric acid hydrolysis	157 ± 24	5.7 ± 1.6	(Costa <i>et al.</i> , 2014)
Bleached kraft bagasse pulp	Sulphuric acid hydrolysis	7.5–16.6	143.4–202.5	(El-Wakil <i>et al.</i> , 2015)
Raw cellulose	Sulphuric acid hydrolysis	~5	~100	(Jebali <i>et al.</i> , 2015)
Rice straw	Sulphuric acid hydrolysis	Average thickness 4.7 ± 1.3 ; average width 6.4 ± 1.2	143 ± 31	(Jiang and Hsieh, 2014)
Cellulose nanofibers	Sulphuric acid hydrolysis	~7	~370	(Mondragon <i>et al.</i> , 2015)
Mulberry pulp	Sulphuric acid hydrolysis	40–50	200–350	(Reddy and Rhim, 2014)
Cotton linter	Sulphuric acid hydrolysis	~12	~177	(Morais <i>et al.</i> , 2013)

and Kitchens, 2012; Cho and Park, 2011; Costa *et al.*, 2014; El-Wakil *et al.*, 2015; Jebali *et al.*, 2015; Jiang and Hsieh, 2014; Mondragon *et al.*, 2015; Reddy and Rhim, 2014; Morais *et al.*, 2013). Leao *et al.* reported preparation of cellulose nanocrystal from sugarcane bagasse fibers. Prior to nano-cellulose extraction, fibers are pre-treated with sodium hydroxide or sodium chloride. Afterwards, cellulose nanocrystals can be obtained by sulphuric acid hydrolysis. Chemical composition and morphology analysis revealed that obtained cellulose nanocrystal exhibiting hemicellulose and lignin removal, nano dimension of 8–12 nm, high crystallinity and low thermal stability (Leao *et al.*, 2017). Orue *et al.* reported extraction of cellulose nanocrystal from office waste papers. CNCs are extracted by alkali pre-treatment, followed by acid hydrolysis. Concentration of alkali solution influences properties of CNCs. CNC extracted with 2 wt% of NaOH solution treatment and subsequent acid hydrolysis exhibit cellulose I crystalline structure, and around 40% increase of crystallinity index as compared to initial office waste paper. Whereas, CNC extracted with 7.5 wt% of NaOH solution pre-treatment and subsequent acid hydrolysis shows mixture of cellulose I and cellulose II polymorphs. CNC prepared by using higher concentration of NaOH exhibits poor thermal property (Orue *et al.*, 2017). Dungani *et al.* reported cellulose nanocrystal extraction from oil palm fronds (*Elaeis guineensis*). Before acid hydrolysis, materials are pre-treated with sodium hydroxide/anthraquinone followed by total chlorine free bleaching treatment. Bleaching treatment, prior to acid hydrolysis improved crystallinity index and thermal stability of extracted CNC. CNC contain cellulose I polymorph, and mean diameter and average fiber aspect ratio are 7.44 ± 0.17 nm and 16.53 ± 3.52 , respectively, making it suitable as reinforcing filler for polymer nanocomposite (Dungani *et al.*, 2017).

CNC can be extracted from microcrystalline cellulose by acid hydrolysis. Extracted nanocellulose has rod like structure with average diameter of around 7 nm (Fig. 3), aspect ratio approximately 25 and crystallinity of approximately 82% (Cho and Park, 2011). Costa *et al.* (2014) reported cellulose nanocrystal extracted by using sulphuric acid hydrolysis of licuri leaves which is composed of approximately 68% cellulose, 15.9% lignin and 8% hemicellulose. Transmission electron microscopic image revealed both individual as well as agglomerated CNC.

Cellulose Nanocrystal as a Renewable Reinforcement in Polymer Matrix

Cellulose nanocrystal (CNC) with enhanced mechanical and chemical properties, have gained huge interest as potential of nanofiller for reinforcement in polymer matrix composites (Yanamala *et al.*, 2014). Li *et al.* reported poly (butylene succinate) (PBS)/cellulose nanocrystal nanocomposites fabricated by solution coagulation. Solution coagulation shows improvement in dispersion and distribution of CNC in the polymer matrix, which subsequently improved properties of the composites (Li *et al.*, 2017). Rahimi and Otaigbe presented cellulose nanocrystal reinforced polyamide 6 nanocomposite prepared via ring opening polymerization and subsequent melt extrusion. CNC surfaces were modified with aminopropyl triethoxysilane. Surface modified CNC reinforced composites were compared with neat CNC reinforced composites. Surface modification of CNC improves dispersion of nanofillers in the polymer matrix as well as interfacial interaction between matrix phase and reinforcement phase. Improved dispersion and the development of the strong interfacial layer, subsequently improved solid state mechanical properties of nanocomposites (Rahimi and Otaigbe, 2017). Being its nano dimension and existence of enormous hydroxyl groups on its surface, uniform dispersion and distribution of cellulose nanocrystal in polymer matrix is a challenge for polymer scientist (Fig. 4). Dispersion and distribution of cellulose nanocrystal can be improved by surface modification of cellulose nanocrystals by using various functional groups. Dufresne proposes various approaches for chemical surface modification of CNC. Approaches can be categorized into three distinctive groups such as: (i) substitution of hydroxyl groups with small molecules, (ii) polymer “grafting onto” approaches and (iii) polymer “grafting from” approaches (Dufresne, 2013). Orr and Shofner use various processing

Fig. 3 TEM image of cellulose nanocrystal (CNC) prepared from microcrystalline cellulose by acid hydrolysis. Reproduced from Cho, M.J., Park, B.D., 2011. Fig. 4 Schematic showing: (A) good dispersion and distribution of nano-reinforcement; (B) poor dispersion and distribution of nano-reinforcement and (C) interface between nano-reinforcement and matrix phase.

strategies to achieve good dispersion and distribution of cellulose nanocrystal in the polyethylene-co-vinyl alcohol composite. They have proposed three processing strategies viz. melt processing, solution casting and combination of solution casting followed by melt processing technique. Nanocomposites fabricated by using multi-steps process shows better dispersion of cellulose nanocrystal in the polymer matrix (Orr and Shofner, 2017). In order to achieve homogeneous dispersion and distribution of cellulose nanocrystals (CNC) in the polymer matrix, different strategies can be applied as summarized in Fig. 5 (Dufresne, 2013) and detail information can be obtained from the literature (Dufresne, 2012).

Each building block of CNC contains three hydroxyl groups on its surface. Being its polar character, it is quite difficult to disperse the unmodified CNC into nonpolar polymer matrix. Surface grafting is a useful tool for widening applications of CNC. Mannan *et al.* proposed surface modification of CNC with bifunctional organic molecules having terminal vinyl groups that in-situ copolymerized with ethylene using a constrained geometry catalyst. This hybrid materials compatibilize hydrophobic polyolefin phase as well as hydrophilic CNC, which subsequently enhanced dispersion and distribution of CNC in hydrophobic polymer e.g., polyethylene (Mannan *et al.*, 2016). Espino-Perez *et al.* (2016) presents surface grafting of CNC with aromatic surface grafts using widely employed methods: the creation of urethane linkages, silylation and esterification to enhance adsorption of particular molecules. Mariano *et al.* (2017) reported noncovalent surface modification of CNC with poly(L-lactide) (PLLA)-based surfactants in order to improve compatibility between reinforcement phase and poly(lactic acid) of nanocomposites.

Mabrouk *et al.* presented CNC based nanocomposite prepared by using in situ mini-emulsion polymerization of acrylic monomers on CNC in presence of methacryloxypropyl trimethoxysilane (MPMS) as a coupling agent for a stable nanocomposite dispersion. Silane on surface of the polymer particles enhances adsorption of CNC through hydrogen bonding on polymer particles (Fig. 6). Prior to the film formation, during water evaporation, polymer particles come closer together with CNC being

Fig. 5 Schematic showing different strategies for the processing of CNC reinforced polymer nanocomposites. Reproduced from Dufresne, A., 2013. Nanocellulose: A new ageless bionanomaterial, *Materials Today* 16, 220–227, with permission.

Fig. 6 Schematic representation of CNC entrapment into the polymer matrix of nanocomposite. Reproduced from Mabrouk, A.B., Salon, M.C.B., Magnin, A., Belgacem, M.N., Boufi, S., 2014. physically adsorbed on their surface turned into chemical linkages by condensation reaction between surface silanol group of MMPS and hydroxyl groups of CNC. The whole processes helps to completely entrap the CNC into polymer matrix of the nanocomposites (Mabrouk *et al.*, 2014).

Properties of Cellulose Nanocrystal Reinforced Polymer Nanocomposites

Reinforcement of cellulose nanocrystal in the polymer matrix is an interesting approach to enhance the performance of polymer matrix by fine tuning of their morphology. Specifically dispersion and distribution of cellulose nanocrystal, and in particular, understanding of contribution of polymer matrix/cellulose nanocrystal interface are keys to design high performance nano bio-composites (Espino-Perez *et al.*, 2018). Depending on dispersion (i.e., individualization of nanofillers) and distribution (i.e., spread of nanofillers throughout the matrix) of cellulose nanocrystal in the polymer matrix, there might be four situations viz. (i) poor dispersion and poor distribution; (ii) poor dispersion and good distribution; (iii) good dispersion and poor distribution; and (iv) good dispersion and good distribution of cellulose nanocrystal in the polymer matrix. Fig. 4 shows schematically poor dispersion and poor distribution, and good dispersion and good distribution of cellulose nanocrystal in the polymer matrix. Apart

from dispersion and distribution of cellulose nanocrystal (CNC), interfacial interaction between CNC and polymer matrix is another key aspect for the improvement of nanocomposite properties. In order to improve the interfacial interaction between CNC and polymer matrix, CNC can be modified by various molecules. Each unit of cellulose nanocrystal contains three hydroxyl groups in its structure, which provides the chemist enormous opportunity for the surface modification of cellulose nanocrystal with various organic molecules. Depending on type selected molecules for the modification, CNC surface could be hydrophobic or hydrophilic, hence, could be reinforced to hydrophobic as well as hydrophilic polymer matrix. Strong interfacial interaction is desired in order to properly utilize the cellulose nanocrystal as reinforcement in the polymer matrix, hence, to improve the mechanical properties of polymer nanocomposites. In case of good interfacial interaction between CNC and polymer matrix, stress transfer from matrix to filler and vice versa will be appropriate, and that will improve mechanical properties of resultant composites. Whereas, in case of poor interfacial interaction, CNC's contribution towards resultant mechanical properties of composites will be minor, as there will be void formation (in case of poor interfacial interaction between polymer matrix and CNC) in the interface of CNC and polymer matrix (Mondal, 2018).

Smyth *et al.* reported improvement of mechanical properties of modified CNC reinforced alginate. CNCs were functionalized with 4-pentenoic acid (PA-g-CNCs) by using a solvent free environmental friendly esterification method. Surface grafting by using PA does not affect physical properties viz. crystallinity and dimensional properties of CNC. Reinforcement of functionalized CNCs has improved dry as well as wet mechanical properties of alginate (Smyth *et al.*, 2018). Shin *et al.* showed improvement of stiffness and energy dissipation of CNC reinforced epoxy composite as compared with neat epoxy material. With 5 wt% of CNC reinforcement in the epoxy matrix, storage and loss moduli in glassy region have been increased by 31 and 57% respectively, while thermal property of nanocomposite remained similar to that of the neat cured epoxy material. In their study, surface modification of CNC with a curing agent (Epikure 3140) exhibit no observable advantage to that of unmodified CNC (Shin *et al.*, 2017). Dhar *et al.* reported around 58% improvement of tensile modulus with 2 wt% loading of CNC in the poly(3-Hydroxybutyrate) matrix. Improvement of mechanical property of CNC reinforced composite is due to the strong interfacial bonding between CNC and poly(3-hydroxybutyrate), which was revealed by the fractured morphology (Dhar *et al.*, 2017). In another study, Dhar *et al.* reported polylactic acid grafted cellulose nanocrystal (PLA-g-CNC) nanocomposite films using dicumyl peroxide as cross-linking agent prepared by single step reactive extrusion process. Presence of chemical cross-linking agent led to efficient transfer of load from CNC to PLA matrix, hence, improved tensile strength by 40% and Young modulus by 490% respectively. The developed composites are thermally recyclable for multiple cycles (Dhar *et al.*, 2016). De France *et al.* reported enhancement of mechanical property of poly (oligoethylene glycol methacrylate) hydrogels by reinforcement of CNC. CNC are uniformly dispersed throughout the hydrogel matrix, and enhances mechanical property of hydrogel. With 5 wt% of CNC in hydrogel matrix, 35 fold increases in storage modulus was observed (De France *et al.*, 2016). Tabassi *et al.* reported CNC reinforced starch green nanocomposites. CNC and thermoplastic starch (TPS) possesses similar polysaccharide structure, hence, provide good interfacial interaction between CNC and starch matrix, and as a result of remarkable improvement of mechanical properties could be observed. With 9 wt% of CNC reinforcement in starch matrix, tensile strength of TPS increased from 3.1 to 11.1 MPa, Young modulus from 237.3 MPa to 4.2 GPa, while, glass transition temperature has been increased from 69.2 to 90.7°C (Tabassi *et al.*, 2016). Chang *et al.* reported CNC reinforced polyacrylonitrile (PAN) fiber prepared by gel spinning. 10 wt% CNC reinforcement can increase tensile modulus and strength from 14.5 to 19.6 GPa and from 624 to 709 MPa, respectively (Chang *et al.*, 2015). Iyer *et al.* reported cellulose nanocrystal reinforced low density polyethylene (LDPE) by using solvent less melt mixing method. Green biocomposite shows 69% increase in Young modulus with 10 wt% reinforcement of CNC as compared with the neat LDPE, while, biocomposite retain their elongation at break (Iyer *et al.*, 2015). Dhar *et al.* presents influence of CNC polymorphs for reinforcement capability and ability to form percolated network. CNC II significantly improved Young modulus of polylactic acid based composite, due to the extensive hydrogen bonding with polymer matrix, leading to the enhancement of mechanical and barrier property of composite films, while, the elongation at break decreases for reinforcement of CNC II as compared with reinforcement of CNC I in the PLA matrix (Dhar *et al.*, 2015b). Lin *et al.* reported acetylated CNC (ACNC) reinforced castor oil based polyurethane nanobiocomposite. With 25 wt% ACNC reinforcement in the polyurethane matrix, tensile strength and Young modulus of nanobiocomposite have been increased from 2.79 to 10.41 MPa and from 0.98 to 42.61 MPa, respectively. Whereas, breaking at elongation increased to maximum, with 10 wt% of ACNC reinforcement in the polyurethane matrix of more than twice than that of the control sample (Lin *et al.*, 2013). Lu and Hsieh reported CNC reinforced poly(acrylic acid) nanofiber spun by electrospinning. The Young modulus and tensile stress of PAA/CNC nanocomposite fibers were significantly improved with increasing CNC concentration in the fiber matrix by up to 35 fold and 16 fold respectively (Lu and Hsieh, 2009).

Optimum concentration of CNC is required for the improvement of mechanical property of nanocomposite. Cho and Park reported that with 3% reinforcement of CNC in poly (vinyl alcohol), storage modulus has been increased up to 74%, while, with 5% of CNC in the PVA matrix, 69% increase of storage modulus was observed due to the interaction of CNC with polymer matrix by hydrogen bonding. However, with 7% of CNC reinforcement in the PVC matrix, the storage modulus decreases (Fig. 7) due to the agglomeration of CNC in the PVC matrix (Cho and Park, 2011). Nicharat *et al.* reported improvement of mechanical property of the CNC reinforced polymer nanocomposite. CNC reinforced thermoplastic polyurethane fabricated by melt mixing shows significant improvement of storage modulus to that of unreinforced polymers. Reinforcement of CNC improves stiffness as well as the shape memory behavior of nanocomposite materials (Nicharat *et al.*, 2017).

Xu *et al.* reported crystallization behavior of CNC and acetylated CNC (aCNC) reinforced polylactide (PLA) nanocomposite. Presence of CNC enhanced melt crystallization rate and degree of crystallinity of PLA nanocomposites. Modified CNC improved

Fig. 7 Storage modulus with respect to the temperature for various CNC reinforced PVA nanocomposites. Reproduced from Cho, M.J., Park, B. D., 2011. Tensile and thermal properties of nanocellulose-reinforced poly(vinyl alcohol) nanocomposites, *Journal of Industrial and Engineering Chemistry* 17, 36–40, with permission.

Fig. 8 Schematic representation of barrier property of cellulose nanofiller polymer nanocomposite. Reproduced from Mondal, S., 2018. Review on nanocellulose polymer nanocomposites, *Polymer-Plastics Technology and Engineering* 57 (13), 1377–1391.

melt crystallization and shows dense surface relative to unmodified CNC (Xu *et al.*, 2017). Dense surface can improve barrier property of the nanocomposite. Barrier property of CNC reinforced polymer nanocomposites can be achieved by crystalline nature of CNC and CNC's ability to form percolating network structure with the polymer matrix by strong hydrogen bonding, and all these increases tortuosity path for diffusing mass molecules (Fig. 8). Mass transfer property through dense polymer film would occurred by molecular mechanism i.e., sorption-diffusion-desorption. Decrease of diffusivity would effectively decreases resultant permeability of mass molecules, hence, improved barrier property of the polymer nanocomposite films. Further, with well dispersed and distributed CNC in polymer matrix can reduce the chain mobility of matrix polymer, as a result further decrease of penetrant diffusivity could be achieved (Dufresne, 2013; Mondal, 2018).

Applications of Cellulose Nanocrystal Reinforced Polymer Nanocomposites

Cellulose nanocrystal reinforced polymer film can be used widely for the food packaging. For food packaging and many other applications, barrier properties of film/membrane are important. The purpose of food packaging is to protect food stuffs from external abuses such as physical, chemical, or biological abuses and also preserve the quality of the food contain from the time of manufacturer to the time of consumption (Khan *et al.*, 2014; Nair *et al.*, 2014). Espino-Perez *et al.* reported barrier properties of CNC reinforced polylactide (PLA) nanocomposites with chemically designed interfaces in order to enhance compatibility of constituents and impart mass transport mechanism. Penetrants such as oxygen molecules and cyclohexane are slightly interacting with composite constituents, whereas, water vapor is highly interacting with the CNC, and anisol (an aromatic organic

vapor) is interacting only with designed CNC surfaces. Water vapor causes significant swelling of CNC, and subsequently creates favorable pathways for mass transport, hence, surface grafting of CNC could interfere this phenomena and decreases water transport rate. The specifically designed barrier properties by designing nanocomposite interface could be useful to design CNC reinforced membrane with selective mass transport properties (Espino-Perez *et al.*, 2018).

CNC reinforced chitosan composite can be used to improve ultra violet blocking property of cotton fabric. Composite can be used as efficient and durable UV blocker, and retain the UV blocking property even after 30 times laundering. CNC reinforced chitosan film coating improve mechanical properties, while decreasing the hydrophilicity of modified cotton fabrics (Yang *et al.*, 2018). Yuwawech *et al.* proposed applications of CNC reinforced polyurethane composites for transparent moisture barrier coating for encapsulation of dye sensitized solar cells. Reinforcement of pure and esterified CNC reduces water vapor transmission rate while light transmission values maintained to be above 80%. Mechanical property of polyurethane composite is higher for the esterified CNC reinforced system than the untreated CNC reinforced PU system. Better stability and efficiency of solar cell can be obtained with CNC reinforced PU, which indicates longer lifetime usage (Yuwawech *et al.*, 2017). Liu *et al* reported conductive CNC-polyaniline nanocomposite prepared by in-situ polymerization of aniline HCl onto cellulose nano-whisker. CNC-polyaniline nanocomposite shows improved conductivity as compared with the pure nanocellulose film. Significant improvement of conductivity of nanocomposite film is due to the dense coverage of tiny PANI particles on the surface of CNC. Flexible conductive nanocomposite films could find applications in sensors, batteries, conductive adhesives etc (Liu *et al.*, 2014).

Cellulose Nanocrystal Reinforced Degradable/Partial Degradable Renewable Nanocomposite Materials

Plastic waste disposal become an ever increasing concern in the planet earth, due to non-degradable nature for most of synthetic plastics derived from petroleum based resources (Al-Maaded *et al.*, 2012; Al-Salem *et al.*, 2014; Briassoulis *et al.*, 2014; Gobbi *et al.*, 2017; Mourshed *et al.*, 2017; Quartey *et al.*, 2015; Rigamonti *et al.*, 2014; Subramanian, 2000). Hence, synthetic plastic/polymers are accumulated over time once discarded after use. On the other hand, degradable plastics are degraded by enzymatic action of the microorganism as well as hydrolysis of long polymer chains (Barragan *et al.*, 2016; Chinaglia *et al.*, 2018; Rujnic-Sokele and Pilipovic, 2017; Iwata, 2015; Jiang *et al.*, 2015; Watanabe *et al.*, 2014). Nondegradable synthetic polymers can be partially/ completely degradable by incorporation of renewable reinforcements such as various cellulosic nano-reinforcements. Abraham *et al.* reported biodegradation of natural rubber and nanocellulose based nanocomposites. Biodegradation of nanocellulose reinforced rubber nanocomposites are shown in Fig. 9. Fig. 9 shows that biodegradation of nanocomposites accelerated with the increase of nanocellulose content in the rubber matrix possibly due to the accumulation of microorganism in peripheral

Fig. 9 Scanning electron microscopy (SEM) images of natural rubber (NR)/nanocellulose composite during the final stages of biodegradation. (A) 7.5% non-cross linked composite (B): 10% cross linked composite (C): standard cross linked matrix (without filler). (D): 10% non-cross linked composite. Reproduced from Abraham, E., Elbi, P.A., Deepa, B., *et al.*, 2012. Thomas, X-ray diffraction and biodegradation analysis of green composites of natural rubber/nanocellulose, Polymer Degradation and Stability 97, 2378–2387, with permission.

nanocellulose reinforcements. It is assumed that biodegradation starts from nanocelluloses due to the accumulation of microbes, which subsequently leaves holes and increase surface area for the biodegradation of remaining matrix materials. Each cellulose unit in nanocellulose contains three hydroxyl groups which are active sites for microbes (unless occupied by hydrogen bonding). Their result also shows that non-cross linked composites show a faster biodegradation than their cross linked counterpart. Interconnected network in the crosslinked nanocomposites could hinder the accessibility of microorganism as compared with the noncrosslinked nanocomposites (Abraham *et al.*, 2012).

Cellulose nanocrystal contain enormous hydroxyl functionality on its surface which could attract water molecules as well as microorganisms required for degradation of CNC reinforced nano-biocomposites (Mondal, 2018). Lin *et al.* reported acetylated CNC reinforced poly (lactic acid) matrix based fully biodegradable composite with superior mechanical property and thermal stability. Improvement of mechanical and thermal property of composite is due to the improved dispersion and strong interfacial interaction between reinforcement phase and matrix phase. The performance of ecofriendly nanobiocomposites expand the utilization of CNC derived from renewable resources (Lin *et al.*, 2011). Fig. 10 illustrates, schematically the cellulose nanocrystal reinforced polymer nanocomposite recycling system in nature. Wood pulp can be prepared from tree, afterwards, cellulose nanocrystals can be manufactured by using acid hydrolysis. Thus, CNC is derived as natural renewable resources. Polymer nanocomposites can be composted or land-filled after uses which will decompose into carbon dioxide and water through the action of microorganisms in the ground. Both CO_2 and H_2O are required for photosynthesis of plants.

Conclusion: Challenges of Cellulose Nanocrystal as Reinforcement

Cellulose nanocrystal has abundant resources; therefore, cellulose nanocrystal holds a great promise in a wide verity of applications including reinforcement in the polymer matrix to prepare polymer nano-biocomposites. There is a huge potential for biodegradable polymers and polymer composite/nanocomposite. Therefore, research effort for the optimization of nanocellulose reinforcement in the polymer nanocomposite will be interesting to explore. In this article, author briefly discusses the cellulose nanocrystal as potential reinforcement for polymer matrix composites. However, CNC possesses several challenges as cost effective nano-reinforcement for polymer matrix nanocomposites. These challenges need to be overcome, before we take the cellulose nanocrystal as potential filler for the bulk nanocomposite fabrication and commercialization. At present cost of cellulose nanocrystals are bit higher therefore to reduce cost of cellulose nanocrystal and increase the productivity, novel technically/commercially viable routes for the manufacturing of nanocellulose should be explored. Furthermore, methods to control size of CNC and the reduction of production cost will be interesting research topic as well. Being its nano size, it is very difficult to disperse and distribute cellulose nanocrystal in the polymer matrix. Development of novel processes to improve dispersion and distribution of nanocellulose in the polymer matrix is quite important. In order to overcome the synthetic plastic pollution, more research effort must be paid for cheap and environmental friendly degradable/partially degradable polymer nanocomposites, and cellulose nanocrystal reinforced polymer nanocomposites should be a competitive candidate. More and more research effort must be made for detail study of CNC reinforced polymer nanocomposite to make CNC reinforced nanocomposite a truly renewable one.

Development and Characterization of Aluminum Hybrid Metal Matrix Composites Used in Automotive Applications

Muhammad S Moktar, Hamidreza Ghandvar, and Tuty AA Bakar, Universiti Teknologi Malaysia, Johor Bahru, Malaysia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Today, reducing fuel consumption in the automotive industry becomes the main agenda due to the emission to the environment and awareness on environmental sustainability. In order to address these issues, manufacturers are considering few approaches namely aerodynamic or streamlining design, incorporating lightweight materials such as aluminum alloys and composites (Qin *et al.*, 2005; Jiang *et al.*, 2005). Aluminum matrix composite (AMC) is one of the competitive lightweight materials used in automobile and other industries during the last decades. Hypereutectic Al-Si alloys with high Mg content are in fact an in-situ aluminum matrix composite containing a large amount of hard Mg_2Si particles. The Al- Mg_2Si composite has a potential as a material for automobile brake disks because the intermetallic compound of Mg_2Si exhibits high melting temperature, low density, appropriate hardness, low thermal expansion coefficient and reasonably high elastic modulus (Zhang *et al.*, 2000; Jing *et al.*, 2009). Compared to conventional ex-situ processes, in-situ technique produces composites with clear interface, better wettability and more even distribution of reinforcements within the matrix. Besides, in-situ method provides reinforcements which are thermodynamically stable since they are the product of reactions within the molten matrix alloy (Ghandvar *et al.*, 2018). However, the Al- Mg_2Si composite has low temperature brittleness and deficient wear resistance, which limit its application. SiC is also the most commonly used reinforcement phase in aluminum matrix composites (Mahmoud *et al.*, 2008; Sakthivel *et al.*, 2008; Song and He, 2010) due to its excellent properties such as higher melting point, higher hardness, better specific strength, excellent wear resistance good wear resistance compared to aluminum alloy (Lee *et al.*, 2001). The combination of aluminum with reinforcement particles is expected to extend the service life of the structures and also to improve the performance of the structure, especially for operations at elevated temperatures. Stir casting is a simple and cost effective method to fabricate the ex-situ aluminum MMCs compared to other fabrication processes. However, various conventional ex-situ processes of fabricating Al-SiC composites have some of the inherent problems, such as poor wettability of the reinforcement, reaction of matrix-reinforcement interface, and inhomogeneous distribution of SiC particles in the matrix (Madarasz *et al.*, 2011). Wettability in stir casting is the interface relationship between the matrix and the reinforcements. It can be defined as the ability of liquid to cover the solid surface, in this case, the reinforcement particles. In addition, wettability can be considered as measure of interface bonding between the matrix and the reinforcements, since different properties of materials within the composite cause discontinuities within the composite (Dutta and Surappa, 1998). It is suggested to add magnesium to improve wettability between SiC particles and the matrix (Nagarajan *et al.*, 1999). In addition, according to previous studies, the SiO_2 layer on the surface of SiC reacts with the Al matrix and Mg that segregates on the interface to form $MgAl_2O_4$ and Si (Lee *et al.*, 2000, 1999; Shen *et al.*, 2009), which prevents the formation of Al_4C_3 and results in the improvement of wettability of the Al-SiC system. Some previous studies have been conducted on the microstructure evolution of Al-SiCp composites (Dutta and Surappa, 1998; Nagarajan *et al.*, 1999). Nagarajan *et al.* (1999) reported that an increase in SiC volume fraction led to a reduction in the size of eutectic Si and also changed its morphology from needle-like to equiaxed, and that SiC particles were found to have negligible influence on DAS. Dutta and Surappa (1998) studied the solidification behavior of Al/Cu-SiCp composite under multi-directional solidification conditions. It was reported that SiCp promoted grain refinement in the matrix in the absence of convection, and matrix dendrite arm spacing (DAS) was not significantly altered by the presence of SiCp. However, there is limited experimental study on the effects of SiC particle addition on the microstructure and tensile properties of Al- Mg_2Si in-situ composites. Therefore, the aim of present study is to characterize the microstructure and elucidate the tensile properties results of the fabricated hybrid reinforced Al matrix composites through the Mg_2Si in-situ synthesis in melt combined with the SiC ex-situ stir casting at different contents of SiCp. This would improve not only the deficient wear resistance of Al- Mg_2Si composite, but also the machinability of SiC/Al composite.

Experimental Procedure

To prepare Al-20 Mg_2Si -2Cu in-situ composite ingot, commercially ADC12 alloy, magnesium (ingot, >98.0% purity) and aluminum (ingot, >98.0% purity) were used. In order to prepare the hybrid composite Al/(Mg_2Si + SiC), firstly, the SiC particles (>99% purity, 10–30 μm) (Fig. 1) were peroxidized at 800°C for 2 h to obtain a better wettability (Lee *et al.*, 2000, 1999). The mass fractions of SiC particle addition were set at 0 wt%, 5 wt%, 10 wt% and 15 wt%, respectively. Secondly, About 300 g of Al-20 Mg_2Si composite ingot was melted in a graphite crucible in an electric resistance furnace. Then the pre-heated SiC particles were added into the Al-Si-Mg melt at 750°C with a stirring action, in which the stirring condition for the fabrication of Al/(Mg_2Si + SiC) composite was: stirring speed of 500 r/min and stirring time of 15 min. Subsequently, after holding for 15 min, the composite melts were reheated to 720°C, and poured into steel die to produce cylindrical samples with 30 mm thickness.

Parallel to casting of test samples, around 100 g of melt was poured in pre-heated ceramic mold (500°C $\pm$ 15 min) for thermal analysis. The temperature-time data was recorded using an EPAD-TH8-K high-speed data acquisition system linked to a computer

Fig. 1 (a) SEM micrograph of SiC powder used to fabrication of MMCs, (b) high magnified micrograph of SiC particles with corresponding (c) EDS spectra and (d) XRD analysis.

with DEWE Soft 7.5 at a dynamic rate of 100 Hz/ch. FlexPro10 data analysis software was used for smoothing the curves and plotting the cooling curve, first (dT/dt) and second derivative (d^2T/dt^2) curves for the extraction of thermal information.

The flat tensile test bars were produced out of the solidified rods and prepared according to ASTM E8/E8M-13. Tensile tests were carried out using an Instron universal mechanical testing machine (5982), equipped with a strain gauge extensometer, at a constant crosshead speed of 1.0 mm/min at ambient temperature.

Metallographic specimens were prepared through standard routines and examined using optical and SEM microscopy to observe the features of the Mg_2Si phase and SiC particles in the composites. The microstructure characteristics of the specimens were examined with a scanning electron microscopy (Philips XL40); coupled with energy dispersive spectroscopy (EDS), while the

Fig. 2 Cooling curve and corresponding first and second derivative curves of (a) Al-20%Mg₂Si, (b) Al/(Mg₂Si + 5 wt% SiC), (c) Al/(Mg₂Si + 10 wt% SiC) and (d) Al/(Mg₂Si + 15 wt% SiC).

mean size of Mg₂Si particles was analyzed by a quantitative analysis system (i-Solution image analyzer). The phase constituents were analyzed using X-ray diffraction (XRD) (PHILIPS binary diffractometer with Cu- α radiation application).

Results and Discussion

Thermal Analysis

Typical cooling curves and first and second derivative curves of Al-20%Mg₂Si composite without and with different percentages of SiC particles are shown in Fig. 2(a-d). These curves have major importance as they indicate the behavior of the composites during solidification process and the effect of the addition of different concentrations of SiC reinforcement on the nucleation temperature of Mg₂Si phase. When the SiC reinforcement is added to Al-Mg₂Si composite, the nucleation temperature of Mg₂Si decreased especially for high percentages of SiC. As depicted in Fig. 2(a), the nucleation temperature (T_N) of Al-20%Mg₂Si is 656.7°C. With addition of 5, 10 and 15 wt% SiC into Al-20%Mg₂Si the nucleation temperature (T_N) of Mg₂Si decreased to 653.5°C, 650.5°C and 648.1°C as indicated in Fig. 2(b-d) respectively. This may be due to the fact that the addition of reinforcements to the matrix leads to a shift in the phase diagrams. Hence, the changing in the eutectic, eutectoid or peritectic points may occur (Daoud and Abo-Elkhar, 2002).

Microstructure Examination

Fig. 3(a) shows the as-cast microstructure of the Al/(Mg₂Si + 10 wt% SiC) composite. As observed the structure of the composite consists of α -Al as matrix and Mg₂Si and SiCp as the reinforcement particles. Furthermore, the EDS results of Mg₂Si and SiC particles are depicted in Fig. 3(b) as indicative of presence of these compounds in the MMCs.

Fig. 3 (a) As-cast microstructure of Al/(Mg₂Si + 10 wt% SiCp), (b) The EDS results of Mg₂Si and SiC reinforcement particles.

Furthermore, Fig. 4 shows the XRD patterns of Al-Mg₂Si and Al/(Mg₂Si + 15 wt% SiCp) hybrid composite. The XRD result in Fig. 4(a) reveals that the constitutions of the Al-Mg₂Si composite consist of Al and Mg₂Si phases. When SiC particles are present in the composites, the constitutions of Al/(Mg₂Si + SiCp) composites contain the aforementioned phases as well as SiC phase (Fig. 4(b)).

Fig. 5 shows the microstructures of Al/(Mg₂Si + SiCp) composites with different SiCp contents. As shown in Fig. 5(a), The Mg₂Si phase is in coarse dendritic shape with an average particle size of 70 μm. From Fig. 5(b) through Fig. 5(d), microstructural changes could be observed. When 5 wt% and 10 wt% SiC particles were added into Al-Mg₂Si composite, the morphologies of Mg₂Si particles in the prepared samples remained polygonal, and the shape was relatively regular and the size decreased to 40 μm and 30 μm, as shown in Fig. 5(b) and Fig. 5(c) respectively. Nevertheless, as shown in Fig. 5(b), the hybrid composite contains 5 wt% SiC contains some porosities in the structure. The existence of porosity is due to entrapment of air during stirring process. With increasing the content of the SiC particles from 10 wt% to 15 wt%, the morphology of Mg₂Si particles was changed to quadrangular with a decrease in size from 30 μm to 20 μm, as shown in Fig. 5(d). It can be concluded that an increase in SiC particle content can lead to grain refinement of Mg₂Si particles. However, as shown in Fig. 5(d) and Fig. 6 although the Mg₂Si particles distributed uniformly in the matrix, with increasing the contents of SiCp to 15 wt%, the agglomeration of SiC particles occurs as shown in Fig. 5(d) (yellow circle) which could decrease the mechanical properties of the composite.

Fig. 4 XRD patterns of Al-20%Mg₂Si composites in (a) base and (b) with 15 wt% SiCp addition.

Fig. 5 SEM micrographs of hybrid MMCs with different SiC contents: (a) 0 wt% SiC (b) 5 wt% SiC (c) 10 wt% SiC (d) 15 wt% SiC.

Effect of SiC Particle Addition on Refinement of Mg₂Si Particles

In the Al-Si-Mg melt, the primary Mg₂Si begins to precipitate and grow up with the decreasing of temperature, leading to the gradual decrease of Mg and Si contents. Accordingly, the Al content gradually increases. It is very obvious that the Mg₂Si forms in the melt with a lower content of Mg and Si and a higher content of Al. As a result, there are Al dendrites surrounding the primary Mg₂Si, as shown in Fig. 5(a). When SiC particles were added into the Al-Si-Mg melt, the size and morphology of primary Mg₂Si changed. Guo *et al.* (1997) found that there was enrichment of Mg element at the Al/SiC interface. In the present study, SiC was

Fig. 6 SEM micrographs of hybrid MMCs with 15 wt% SiCp in higher magnification illustrating the clustering (agglomeration) of SiC particles in the matrix alloy.

Fig. 7 SEM micrograph of Al/(Mg₂Si + SiC) hybrid composite indicating the heterogeneous nucleation of Mg₂Si on SiC particles.

oxidized in air at 800°C, and the SiC reacted with the oxygen to form a thin layer of SiO₂ on the surface of SiC. Furthermore, the SiO₂ layer reacted with Al and Mg within the matrix alloy, forming MgAl₂O₄ and Si at the expense of the SiO₂ layer, according to the reaction given by Eq. (1) (Lee *et al.*, 2000, 1999).

MgAl₂O₄ crystal formed as a result of this interfacial reaction is face-centered cubic structure with lattice constant of $a = 0.8085 \text{ nm}$ (Chawla and Shen, 2001).

According to the interface lattice mismatch theory, when the atomic arrangement and inter-atomic distance on the surface of solid phase substrate are close to that of newly formed crystal nucleus, the solid-liquid interfacial free energy is very low, and the external solid phase has a very strong capability to serve as site for heterogeneous nucleation Zhang *et al.* (2000) found that the calculation value of planar mismatch δ between [110] MgAl₂O₄ and [010] Mg₂Si is 0.109, namely the interfacial-bonding mode between MgAl₂O₄ and Mg₂Si is semi-coherent, and so MgAl₂O₄ formed at the SiC surface may serve as favorable sites for the heterogeneous nucleation of Mg₂Si phase. As a result, some Mg₂Si particles cling to SiC particles and grow up, and others nucleate independently and grow up in the liquid phase. The morphologies of Mg₂Si and SiC particles in (Mg₂Si + SiCP)/Al composite are shown in Fig. 7. It is obvious that primary Mg₂Si particles cling to SiC particles. Thus, with the increasing of the number of SiC particles, more nucleation sites can be provided for the primary Mg₂Si phase, essentially leading to refinement of grain size. On the other hand, the presence of SiC particles restricts the growth of Mg₂Si due to their mechanical obstruction. In short, it is the factors discussed above that cause refinement of Mg₂Si particles.

Tensile Properties

The ultimate tensile strength and percentage of elongation of the MMCs without and with different percentages of SiC are given in Fig. 8. It is noted that with addition of 5 wt% SiC to Al-20%Mg₂Si, the UTS decreased from 67.61 MPa to 53.58 MPa, similarly, the El (%) decreased from 0.57 to 0.42. Although addition of 5 wt% SiC particles leads to refinement and modification of Mg₂Si particles by decreasing in Mg₂Si size and transformation in the adverse structure of Mg₂Si (dendritic morphology to polygon) (Fig. 5(b)), the presence of porosity in the composites due to gas entrapment during stirring the melt, when compared with the Al-Mg₂Si composite is one of the reasons for lowering the tensile properties of the fabricated hybrid composite. In fact, the increase of pores in the composite would create more sites for crack initiation and hence lowers down the load bearing capacity of the composite. The structures and

Fig. 8 (a) UTS and (b) El (%) of fabricated MMCs.

Fig. 9 Engineering stress-strain curve of Al-20%Mg₂Si composite (Base) and hybrid MMCs with different percentages of SiCp.

properties of the interface between the particles and matrix alloys play a significant role in controlling the tensile properties of the composites. However, as observed in Fig. 8, with increasing the SiC content to 10 wt%, the tensile properties increased as the UTS and El (%) of fabricated MMCs increased to 77.45 MPa and 0.6 respectively. The presence of good interfacial bonding and lower content of porosity in the structure of MMC compared to 5 wt% MMC is the reason for improving in the tensile properties of the Al/(Mg₂Si + 10 wt% SiC). In fact, the SiC reinforcements are tend to support the load applied on the matrix through direct strengthening mechanism. The mechanism supports the composite by transferring the applied load from the matrix to the SiC reinforcements through their interface. Hence, good interface between the matrix and the reinforcements is required so that the load can be transferred effectively (Chawla and Shen, 2001). As observed in Fig. 8, the hybrid Al/(Mg₂Si + 15 wt% SiC) with the most refine Mg₂Si particles with quadrangular shape (Fig. 5(d)) compared to other fabricated MMCs shows the lowest tensile properties; the UTS and El (%) of the fabricated composite decreased to 34.11 MPa and 0.3 which can be due to presence of agglomerated SiC in the structure of composite (Figs. 5(d) and 6) which in turn decreased the tensile properties of the MMC.

Fig. 9 shows the stress versus strain curve for the Al-20%Mg₂Si in-situ and hybrid composites with different contents of SiC. The Al-20Mg₂Si in-situ composite (base) exhibits more ductile properties compared to the others. The tensile results demonstrate that

Fig. 10 SEM micrographs of fracture of hybrid MMCs with different SiC contents: (a, b) 0 wt%, (c, d) 5 wt%, (e, f) 10 wt% and (g, h) 15 wt% in low (left) and high (right) magnifications.

the increase in SiC particles transforms the ductile properties to brittle properties. The decreases in the ductility of the hybrid composites may be related to the presence of porosity in the composites, in comparison to that in the Al-Mg₂Si alloy. Porosity can serve as an effective stress concentration site, which promotes crack initiation and results in decreasing the proportion of the composites. In addition, the plastic deformation of the composite may be prevented by the particles and the larger differences in the CTEs between Al alloy and the particles lead to thermal mismatch. The stresses generated due to this thermal mismatch put the particles into compression and the matrix into tension. These residual stresses would probably contribute for the brittle nature of composites (Arsenault, 1984; Taya *et al.*, 1991).

Fractography

Fig. 10(a–h) depicts the SEM fracture surfaces of the MMCs after tensile test with 0, 5, 10 and 15 wt% SiC addition in low (left) and high (right) magnifications. **Fig. 10(a,b)** illustrates a typical surface of the in-situ Al-20Mg₂Si composite with cellular fracture (Lewandowski *et al.*, 1989) as a result of cleavage in fracture planes of coarse Mg₂Si particles. Furthermore, as observed in **Fig. 10(b)**, the fracture occurred in the Mg₂Si particle. It is because in in-situ composite, the stress concentration is easy to localize near the sharp tips of the coarse dendritic Mg₂Si particles; as a result, a sharp crack with a critical length was provided which caused brittle fracture. As shown in **Fig. 10(b)**, these areas are potential sites for nucleation and propagation of micro-cracks through the coarse Mg₂Si directly (due to their intrinsic brittleness) or along the interfaces between matrix and Mg₂Si crystals or eutectic cells which undoubtedly decreased the ductility of the matrix. The fracture surface of Al/(Mg₂Si + 5 wt% SiC) is shown in **Fig. 10(c and d)**. As observed in **Fig. 10(d)**, the particle–matrix interface debonding can be seen in the fracture surfaces of the composite. Cavities formed due to porosity are also observed in the composite fracture surface. It has been reported (Lewandowski *et al.*, 1989) that the fracture of MMCs depends on particle cracking, particle–matrix debonding or grain boundary fracture, which are influenced by the local stress field, the presence of the interface inhomogeneities, structural alterations in the matrix close to the interface or flaws around and inside the particles. Strain localization at the sharp corners of particles may also lead to debonding between the particle and matrix, which is a possible source of the failure of the present composite. The fracture surface of Al/(Mg₂Si + 10 wt% SiC) is depicted in **Fig. 10(e and f)**. Compared to MMC with 5%SiC, this hybrid composite illustrated a better fracture behavior as some dimples are observed on the fracture surface indicating ductile fracture. Furthermore, less voids or porosity are observed on the fractured surface of this MMC due to uniform distribution of the SiC particles in the matrix and good interfacial bonding in the interface of SiC and Al matrix as a result of proper wettability of SiC particle in the matrix alloy. Therefore, the SiC reinforcements can provide better support for the matrix when the stretching load is applied. Particle cracking can be observed in SiC particle in the fracture surface (**Fig. 10(f)**) which indicates good bonding, as the result the highest tensile strength is recorded for this composite (**Fig. 8**). However, the fracture surface of Al/(Mg₂Si + 15 wt% SiC) in **Fig. 10(g, h)** shows clear cleavage on fracture surface of the hybrid composite which is due to improper wettability between SiC and the matrix and hence agglomeration of SiC particles occurred which signifying that particle–matrix interface debonding (**Fig. 10(h)**). Furthermore, the large differences of CTEs between the Al alloy and SiC particles produce large thermal mismatch stresses on cooling from processing temperature to room temperature, which may result in generating microcracks at the interface between the matrix and particles. Consequently, the composite becomes brittle, stress concentration becomes more liable to occur and the ultimate tensile strength and ductility decrease. In summary, it is thought that cracks mainly initiate at particle–matrix interface, propagate through the matrix and link up with other cracks leading to failure of the composites.

Conclusion

By adding SiC particles into Al-Si-Mg melt, Mg₂Si and SiC particles hybrid reinforced Al matrix composites with relatively homogeneous distribution of the reinforcement Mg₂Si and SiC particles can be obtained through Mg₂Si in-situ synthesis in melt combined with SiC ex-situ stir casting. With increasing the content of the SiC particles from 5 wt% to 10 wt%, the morphologies of the primary Mg₂Si particulates in the prepared samples remain polygonal, but the size of the primary phase decreases slightly. However, the morphologies of the primary Mg₂Si particulates change to quadrangular with a decrease in size from 30 µm to 20 µm when the SiC particle addition reaches 15 wt%. In comparison to those of Al-Mg₂Si composite, the Al/(Mg₂Si + 10 wt% SiC) showed the highest tensile properties in term of UTS and El (%), however, Al/(Mg₂Si + 5 wt% SiC) and Al/(Mg₂Si + 15 wt% SiC) depicted low tensile properties due to existence of porosity and agglomeration of SiC particles in the fabricated composites. In Al/(Mg₂Si + 5 wt% SiC) and Al/(Mg₂Si + 15 wt% SiC) produced composites, cracks may initiate at particle–matrix interface and SiC clusters respectively, propagate through the matrix and link up with other cracks, leading to failure of the composites. However, in Al/(Mg₂Si + 10 wt% SiC) fine dimples and particle cracking was observed on the fracture surface indicating suitable interfacial bonding between SiC and matrix.

Introduction

Green computing refers to the efficient use of computers and their resources during their lifetime and in conjunction with minimizing environmental impact (e.g., the reuse of resources to prevent air pollution, water pollution and to reduce electricity consumption, etc.) to maximize economic efficiency and viability. The recent development of green computing offers significant advantages for organizations to outsource their Information and Communication Technology (ICT) infrastructures, including telecommunications.

At the same time, the widespread use of datacenters used to establish green computing environments creates an ever-increasing carbon footprint and draws additional energy consumption thereby raising environmental concerns. Researchers have focused on developing energy management proposals to reduce massive energy consumption from telecommunication networks. One of the growing concerns of green computing is the lack of data security when green vendors store data. To protect data and information, vendors need to deploy additional hardware/software systems to provide sufficient security measures, which increases the demand of energy consumption.

The research and industry focus is on the development of energy-efficient computers and telecommunication infrastructures. In addition, how these developments may vary at a low hardware level to a high software level is of concern. The majority of the research proposals aim at energy efficiency for Cyber-Physical Systems (CPSs). The research suggests there is an unresolved gap in the security aspect of these systems. This article focuses on the development of green computing solutions to enhance security in Mission Critical Cyber-Physical Systems (MC-CPSs), and introduces Seddulbahir as an evolutionary green computing security solution.

The organization of the rest of the article follows: Section “Mission Critical Cyber-Physical Systems (MC-CPSs)” provides an overview on mission critical Cyber Physical Systems and elaborates on the details and main characteristics of these systems. Section “Renewability, Sustainability and Recycling Issues of Green Computing” expands upon green computing solutions for Mission Critical Cyber-Physical Systems. Section “Seddulbahir” introduces the Seddulbahir Firewall-as-a-Service model to enhance a green computing environment. This section also compares the design of this development with the existing systems based on a performance matrix. Section “Conclusion” concludes the study with future recommendations on the usage of outsourced communication security infrastructures.

Mission Critical Cyber-Physical Systems (MC-CPSs)

In recent years, Cyber Physical Systems (CPSs) have become an emerging paradigm for monitoring, controlling, coordinating and managing physical and engineered systems. Examples include an ever-growing number of cyber-connected devices, automated health care systems, smart electricity grids, energy efficient green-clouds and the surveillance of unmanned aerial vehicles (UAVs). CPSs are intelligent systems that are co-engineered to have the ability to interact with a variety of physical components through communication networks (Banerjee *et al.*, 2012). Due to expanding usage and service availability measures, the assemblage of most infrastructures include modern CPS components since cyber-based services have become an inevitable component used in mission critical applications. The typical infrastructure characteristics are fault-tolerant, reliable, safe, and include accessing data in real-time. In addition, their designs survive over time and provide more efficiency, autonomy and reliability compared to manually controlled and loosely coupled systems.

The development of smart and mission critical systems are widespread, and they transfer into our everyday lives. In the health sector, the development of physiological sensors used on humans allows for fast detection of injuries during medical emergencies. In addition, the deployment of such sensors in energy-efficient smart buildings detects the absence of occupants in an area and shuts-down the cooling/heating unit for energy efficiency. The previous are examples of the interaction between our physical environments with embedded systems. A final example of a CPS are UAVs that track, monitor and/or capture an image of a geographic terrain to perform surveillance.

Mission Critical Cyber-Physical Systems (MC-CPSs) are complex integrated systems that entail a group of “systems within systems” (Moholkar, 2014). Such complexity and integration of CPSs may result in different vulnerabilities in terms of safety, security and sustainability. The combination of cyber systems with physical systems within an MC-CPS infrastructure exposes significant inherent vulnerabilities and threats that may raise specific needs and require designers to take certain precautions. A failure of any one system may result in a catastrophic failure of a mission critical infrastructure and service.

For example, a cyber-attack generated against MC-CPSs at a hospital might lead to the untimely delivery of medication to a patient. CPSs that control UAVs or drones have similar vulnerabilities that might lead to the malfunction of UAV control systems/ algorithms and cause UAVs or drones to crash into geographical regions causing a potential loss of civilian lives (Moholkar, 2014).

Maintaining maintenance measures is an important aspect of MC-CPSs since they provide services for extended periods. In addition, resource utilization is another component in maintaining a long operational life. Green energy supported CPSs are more powerful since their lower usage of energy draws from battery or other power sources. The previous advancements result in the increase of a computer/system's life and reduces the cost of operation of a MC-CPS. Furthermore, infrastructure architects carefully address the functionality of MC-CPSs to ensure safety, security and sustainability. Meeting the satisfaction of the previous metrics also depends upon the types of information extracted from the computing unit. Therefore, the design of a secure, safe and sustainable MC-CPS also requires an investigation of the behavioral characterization of the physical environment, which affects the metrics directly.

The violation of security access rules of MC-CPSs and unauthorized access to restricted systems in CPSs of health systems, transportation (air, land, sea, space) infrastructures, water infrastructure systems, gas and smart electricity-grid infrastructures can lead to a loss of CPS security. As a result, there may be significant negative and hazardous impacts in a society, including the loss of privacy, potential physical harm and personal discrimination and/or abuse.

The next section "Renewability, Sustainability and Recycling Issues of Green Computing" elaborates on the renewability, sustainability and recycling issues of green computing. Section "Green Computing Solutions for Mission Critical Cyber-Physical Systems" elaborates on existing solutions and proposals for energy consumption and workload issues and provides insight about existing energy efficient green computing solutions for MC-CPSs. Next, the introduction of Seddulbahir's design by using Artificial Intelligence (AI) also addresses green computing. The section also covers Seddulbahir's performance metrics such as security, safety and sustainability to ensure security of CPSs to prevent cyber-attacks.

Renewability, Sustainability and Recycling Issues of Green Computing

Green computing can lead to a reduction in energy costs for servers, cooling and lighting. Due to advancements in green computing, the IT industry has especially focused on the improvement of power and cooling issues through the development and processing of new electronic equipment. Worldwide organizations spend a considerable amount of effort to achieve major green computing goals for energy-hungry centers.

Addressing the human factor is one of the greatest challenges of green computing goals in IT. The greatest challenge for a society is to understand the goals and objectives of green computing and only then, can the environment be renewed and sustained. To reduce negative environmental issues organizations propose standards to regulate the environmental effects caused by the IT industry. The Organization for Economic Co-operation and Development (OECD) has published a survey of several countries and industry initiatives on green ICT to avoid environmental changes. In Table 1 below is a list of country agencies and organizations that support green computing and adhere to proposed standardizations and compliances (Raza *et al.*, 2012).

Some of the good practices conducted in the international arena are through international standards such as ISO-14000 and the Occupational Safety Standard (OHSAS-18001) on environmental management. The proposed standards focus on risk, the nature of that risk and the required control of measures for protecting an environment. In the area of equipment disposal, there is no control due to a lack of standard policies on the degradation and reuse the technological scrap. In order to maintain the green revolution, government agencies must focus on the implementation of strong guidelines for scavengers and propose practical "disposal training" as a requirement.

Countries and organizations telecommunication infrastructures rely on complex networks. However, proposed green computing solutions should be universal and simple to apply. Therefore, the proposal of policies and regulatory obedience should be compulsory items for the sustainability of green computing. In addition to this, the proposed green computing technologies must address end-user satisfaction, management re-information and the virtualization of server resources. In the recycling context of the

Table 1 Green Regulations Proposed by organizations and countries

<i>Organization/regulation/program</i>	<i>Country</i>

proposed green computing technologies, the proper disposal of electronic scrap and waste, efficient energy usage, thin client solutions and return on investment (ROI) must be targeted (Harmon *et al.*, 2010).

As a result, the most important factor is to increase public awareness of the governmental initiatives through 'awareness campaigns' on extending sustainability, renewability, recycling and the green computing concept.

Green Computing Solutions for Mission Critical Cyber-physical Systems

Researchers have focused on the development of green computing solutions that satisfy some of the expected properties of Mission Critical Cyber-Physical Systems (MC-CPSs). As mentioned earlier, conventional security precautions are not sufficient to protect the vulnerability of MC-CPSs from attackers (Estevez and Wu, 2016). Through access to sensors, an attacker could potentially tamper with a smart data center resulting in an air conditioner overload. One of the solutions proposed by researchers is to model an energy management strategy for MC-CPSs. The main aim is to create a balance between the produced-available power and the power demand of a workload (Ge *et al.*, 2014). A proposed solution named Dynamic Power Balance Strategy (DPBS) coordinates both the workload and the battery usage to ensure the sustainability of energy computing in an energy management system for a specific device.

Researchers have proposed the cooperative differential game model in order to elaborate on the trade-off problem between bandwidth and energy (Fuhong *et al.*, 2014). Earlier, Miao *et al.* (2012) proposed a model based on bandwidth and energy. The research model proposed by Pan *et al.* (2015) aimed to control energy modes of various appliances in order to put them into energy-saving mode in case of an idle state of any device.

Since there are a significant number of equipment used and deployed in a telecommunication operator infrastructure, additional effort addresses the telecommunication sector and the development of energy efficient communication infrastructures and MC-CPSs. The model developed by Lin *et al.* (2011) focused on real-time monitoring for energy consumption and real-time controlling of the energy state at base stations for telecommunication operators to make intelligent decisions based on the environment's current state. A linkage created between the monitoring devices of MC-CPSs and power management systems solved the problem.

Some research exposes the need for energy efficiency of IoT networks and claims that the raise in energy consumption is due to the communication between massive counts of sensors used in IoT networks. In order to achieve energy efficiency for an IoT, Sundar Prasad and Kumar (2012) proposed scheduling an algorithm for the participating IoT nodes to have the ability to decide to be active or not based on the information gathered from its neighbors. Deployment of such algorithms may increase the performance of the nodes, but not the security. Chao *et al.* (2011) have discussed the same matter since security is a concern for the IoT. Later, Chao and Wu (2015) succeeded in the deployment of an algorithm with specific architecture and force for IoT nodes to consume energy only when necessary.

Zhou *et al.* (2016) proposed the deployment of an optimized energy efficient protocol called Enhanced Channel-aware Routing Protocol (ECARP) for underwater operations. The new improvements and optimization of a protocol focused on improved data transmission and improved routing that is targets and explores vast ocean space.

As mentioned above, the proposed green solutions for MC-CPSs by the researchers focuses on specific architectures and/or requires deployment of many nodes to work efficiently in a complex environment. The majority of models predominately focus on energy consumption and energy efficiency, and a lack of security remains as a gap in the field. In order to close this gap, the next section details a green computing solution model for Seddulbahir.

Seddulbahir

Firewall as a Service (FaaS) technologies provide security at a lower cost and with lower maintenance, lower complexity and higher efficiency, which attracts organizations and has become their first choice as a solution. Apart from this, virtualization becomes another opportunity to decrease the cost of hardware and software deployed for an organization's communication infrastructure. However, the research shows that in practice, there is a difficulty in managing and establishing security in a virtualized environment so there is a need for advancements in security tools to monitor, debug and control malicious network traffic was inevitable.

Seddulbahir is a Firewall as a Service security system developed by researchers in Turkey to provide analysis of incoming/outgoing flow of network traffic within the country's MC-CPSs for security measures (Sari, 2018). It was developed and simulated to control a variety of different communication infrastructures in sectors ranging from hospitals to universities. The initial architecture of Seddulbahir, deployed in a Wide Area Network (WAN), monitored, debugged, interfered and controlled malicious network traffic, as illustrated in Fig. 1 below.

Upon further development, the deployment of Seddulbahir in a Virtual Machine (VM) environment in organizations provides integrated enhanced security and energy-efficiency. Companies using a VM environment and wishing to avoid purchasing additional security hardware and software has lowered their deployment and maintenance costs for the entire system security.

As illustrated in Fig. 1 above, the performance metrics of the Seddulbahir system in a WAN indicated success above the expected level (Sari, 2018, 2019). In order to provide services for lower level network architectures, further development and

Fig. 1 WAN deployment model of Seddulbahir.

deployment in a bare-metal server that hosts VMware ESXi (formerly ESX) operating systems can provide a stable virtualization environment.

Even though vast amounts of research exists on achieving energy efficiency, there remains a serious gap in the security of MC-CPSs. The widespread deployment of Seddulbahir provides a variety of advantages in terms of energy efficiency, performance, reliability, maintainability, monitoring, control and security.

The deployment of the Seddulbahir firewall system in a network environment can communicate with virtual machines, proxy servers, Windows/Linux Servers (Ubuntu 18.06) and vSphere Server. The ESXi 6.0 operating system is used to provide virtualization services on the bare-metal server. The bare metal server best selected is the IBM x3500 M4 with a configuration of Intel Xeon E5 2620 V2 CPU, 96 GB ECC RAM, 2 TB SSD. The deployment of Seddulbahir requires very basic resources in VM environment. The deployment also requires an Ubuntu 18.06 OS with only 8 GB ECC RAM and with a single core virtualized CPU and 20 GB of storage. The deployment infrastructure model of Seddulbahir on a VM environment is illustrated in [Fig. 2](#) below.

As shown in [Fig. 2](#) above, the VMware systems are installed on a bare-metal IBM X3500 M4 server, which is illustrated as “Source ESX host” in the [Fig. 2](#). In this scenario, the ESXi host provides virtualization on the bare-metal server for 4 interconnected networks, which are VM Campus wing A, B, C and D.

All of the virtual machines hosted in these networks are connected to each other through virtual switches. Each network contains virtual machines, proxy servers, Windows/Linux servers and a Seddulbahir node. The Seddulbahir node acts as an intermediary between the internal and external network flow to monitor the network traffic.

The incoming and outgoing traffic flow is inspected based on the “Rule Engine” of Seddulbahir, which is developed based on the Radial Basis Function (RBF). The rule engine contains set of rules to differentiate malicious/benign traffic and blocks the corresponding flow based on specific features of the incoming package such as flags, ip src, src port, dst port, seq, checksum, ip dst, ttl, ackseq and data. There is the possibility to inspect and differentiate between binary based (e.g., dns) protocols, text-based protocols (e.g., http), packet-based protocols (e.g., ip) and stream-based protocols (e.g.) in the network flow. All of these features eliminate the necessity of different hardware and software deployments. The entire network can be controlled with a deployment of a single appliance of Seddulbahir on the IP address assigned as 172.52.9.56.

The Local Area Networks (LAN) with an IP address that blocks assigned protocols of 10.56.5.1, 10.56.6.1, 10.56.7.1 and 10.56.8.1 are controlled with separate instances of Seddulbahir, and these appliances are dedicated to their networks, which has no interaction with other Seddulbahir appliances.

Since the entire security system is integrated with many modules, the tshark tool is used as a packet capture module. There are a variety of other details related with Seddulbahir and provided by researchers ([Sari, 2018, 2019](#)). The system has a remote connection and access features to provide remote management possibilities. Therefore, the system administrator can access a firewall interface through the web and manage the entire network in a VM environment. The Seddulbahir deployed on the Ubuntu 18.06 server appliance with a dedicated dashboard developed to measure a variety of performance metrics is illustrated in [Fig. 3](#) below.

This dashboard contains different features, menus and sub-menus to provide accessibility monitor and control the entire system security and performance. The developed dashboards illustrate the system performance and the overall power

Fig. 2 VM deployment infrastructure of Seddulbahir.

consumption. The load and performance of each system component can be monitored without the need of any additional hardware installations.

- The Dashboard Menu contains: Overview, Traffic Summary, Network Snapshot and System Performance,
- Inventory Elements Menu contains: Devices, Interfaces, IP Groups, Interface Groups,
- Alarms Menu contains: Active Alarms, All Alarms, Events, Create Alert Profile,
- Maps Menu contains: Attack Maps, Google Maps, Zoho Maps,
- Reports Menu contains: Forensics, Protocol Distribution, Attack Report, Consolidated Report,
- Attacks Menu contains: General Attacks, Attacker Profiles, DPI (Deep Packet Inspection),
- Rules Menu contains: Rule Engine, Firewall Rules, Add New Rules,
- Settings Menu contains: System Settings, Basic Settings.

At this point, there are no further details on the system due to limitations and scope of the book. However, there will be further research efforts discussed that will expose the performance results of existing developments in different environments and different layers of networks.

Fig. 3 Dashboard of Seddulbahir.

Conclusion

The rapid growth in the demand of network traffic requires intensive deployment of new hardware/software infrastructures that also address today's global environmental state. Conventional hardware/software infrastructures and bare-metal systems are approaching their capacity and performance limits. Development of security systems must smartly integrate computing, controls, sensing, and networking to transform the joint behavior of elements in an environment-friendly manner while also focusing on sustainability and providing security.

The design of environment-friendly security systems used to enhance green computing and support security, faces many challenges. The design and the development of systems can follow design principles at the deployment level, the traffic routing level, the traffic demand level and the transmission level. To eliminate many challenges, the classification of Seddulbahir as a Next Generation Cyber Firewall (NGCF) can provide lightweight deployment with integrated enhanced security measures that meet at different levels of a communication network.

Deployment of Seddulbahir as a green-security solution or FaaS solution reveals significant advantages. It lowers the amount of workload needed to maintain an infrastructure by lowering the number of IT staff needed to administer/maintain a system, which in turn will increase the efficiency and effectiveness of the business. Additional benefits include an increase in the diversification of job positions by raising the need for data analyst specialists, firewall developers, SOC specialists, and data miners. Finally, there would be a decrease in the cost of energy spent on a system's infrastructure (hardware-software).

Introduction

PEEK has got significant attraction of today's researcher due to its properties like: hot strength, temperature resistivity and good performance in mechanical parameters (Yang *et al.*, 2017; Jin *et al.*, 2017). Virgin PEEK has poor wear resistance but by adding carbon fiber in PEEK these properties can be enhanced. Temperature is also observed as a considerable parameter that can change the wear behavior of PEEK (Lind *et al.*, 2015). Machinability of virgin PEEK is higher as compared to its composite with carbon fiber and glass fiber (GF). The difference of 100 N is observed in cutting of virgin PEEK and PEEK-GF reinforced samples at cutting speed of 50 m/min at feed rate of 0.05 mm/rev (Davim *et al.*, 2010). PEEK polymer shows good fracture resistance as compared to other polymers (Lesiuk *et al.*, 2017). Due to the high strength to weight ratio, PEEK composite is used in clinical dentistry and orthopedic scaffolds. It has been reported that due to lower surface energy and chemical inertness the bonding energy of PEEK composite is low (Tsuka *et al.*, 2017). In case of dynamic loading, coefficient of dynamic friction is found to be directly proportional with load. In case of harsh ambient conditions like high temperature and chemical toxic atmosphere PEEK composite can be used (Zsidai and Kátai, 2016). For the ultrasonic fabrication of PEEK the frequency of 5 MHz is more sensitive for the span of 0.5–10 MHz (Du *et al.*, 2014). The wear rate of PEEK composite is small as well as coefficient of friction in comparison with virgin PEEK (Du *et al.*, 2014). The impact durability of porous PEEK is more as compared to titanium coated PEEK. The surface erosion of porous PEEK is less and no significant change in porosity is observed (Torstrick *et al.*, 2018). The thermal expansion of the PEEK polymer at high temperature create a hindrance in observing wear rate. It was observed during wear test that at starting

time span the wear increase but after some time it remain constant (Kónya *et al.*, 2005). During solidification of PEEK with carbon fiber reinforcement the fiber acts as a nucleation site. The melting and transition temperature of PEKK is found to be 145°C and 337°C respectively by means of differential scanning calorimetry (DSC) testing (Nguyen and Ishida, 1986). Although today mostly body implants use metals like titanium but its long run embedment can create allergic tissue at the emend portion of body. By the replacement of titanium with PEEK this problem can be solved to the great extent (Ma and Tang, 2014). With the reinforcement of

silica fibers into the PEEK sample (30% by weight) the mechanical strength is found to be increased 1.5 times to that of virgin PEEK. Further 1.25 times increase in micro hardness was observed for this reinforcement. Proper adhesive bonding was found to be established among the amorphous fiber of silica and PEEK polymer (Monich *et al.*, 2017). The stress shielding effect is observed when the natural bone is replaced by titanium metals due to significant difference (more than 7 times to that of bone) among the strength of materials. Although PEEK Young's modulus is half to that of bone but by means of fiber reinforcement its strength become very close to human bones. This makes it more desirable polymer that can replace metals in orthopedic implants and lowering the stress shielding effect (Najeeb *et al.*, 2016).

Some studies have been reported on 3D printing of PEEK with fused deposition modeling (FDM) based printers (Vaezi *et al.*, 2018; Yu *et al.*, 2018; Stepashkin *et al.*, 2018). But hitherto very little has been reported on joining of PEEK substrates with resistance welding processes like FSW. This is required for special cases when some trauma patient is operated and fixed with PEEK based scaffolds/implants and after the major surgical operation again because of another injury or stress concentration on the scaffold/joint minor surface cracks are observed in follow up sessions by the surgeon (especially while 3D scanning). For maintenance and repair of small cracks, FSW can be performed on line on the patient with hand held rotating mechanism in place of replacement of scaffold/implant from the patient body (as this will be less painful and less time consuming activity). This study reports the investigations for joining of PEEK substrates with PEEK based consumable rapid tooling prepared in pin shape and processed on conventional vertical milling setup as a novel method.

Experimentation

The virgin PEEK polymer of bio-compatible grade was procured from the local market in the form of fine powder. The melt flow index for selected PEEK grade was 3.01 g/10 min as per ASTM D1238. This powder was molded into cylindrical shape disks with the help of hot mounting machine. Hot mounting machine consist of a chamber that is covered by heaters. These heaters heat the

polymer at elevated temperature and ensure the proper bonding between the filled polymers. The PEEK polymer was filled into the chamber and temperature of 415°C was attained at slow heating. It must be ensured that the air bubbles should not entrap inside the chamber that create porous structure inside the final part. To tackle this problem the chamber was put under high compression that also increase the density of the final product. Fig. 1 shows that lower half portion of the polymer was bonded and converted into solid shape but the upper half of the polymer remained un-bonded. This may be due to lower thermal conductivity of the polymer. Due to this limitation there is a constraint for length of the cylinder made in hot mounting machine. On the other hand the polymers like PLA having more thermal conductivity then PEEK can be made in solid form with more length (approximately double). To overcome this problem PEEK powder was first processed on single screw extruder at temperature of 430°C and FDM feed stock filament was prepared at 100 rpm screw speed. The feed stock filament was prepared of diameter 1.75 ± 0.05 mm and was fed to commercial FDM printer (Make: Prusa i3 MK3S kit) with alteration in print head (temperature range up to 430°C). The in-house prepared feed stock filament was fed to FDM setup and functional prototypes were prepared at 50 mm/sec printing speed, with 04 number of perimeter layers, print bed temperature 110°C and travel speed of 120 mm/s with rectilinear fill pattern.

Fig. 2 shows the cylindrical disks printed by commercial FDM based 3D printer.

For investigations of joining capabilities with FSW, two plates of length 30 mm and thickness 4 mm were 3D printed. The consumable pin of diameter 4 mm was also 3D printed with same material. Fig. 3 shows the 3D printed plates made from PEEK material.

Based upon pilot experimentation, to make joint with friction stir welding, the depth of 2 mm was selected which was sufficient to generate frictional heat and make a strong joint in remaining thickness. The welding time of 20 s was selected that is sufficient to develop material flow to fill the joining interface and proper heating of the joint. The rotational speed of the holder was varied in this investigation. Two rotational speeds 1500 rpm and 2000 rpm were selected for the investigation. It has been observed that

below 1500 rpm joint was not feasible and above 2000 rpm more flash was generated which decrease the strength of the joint. **Fig. 4** shows the fixtures for FSW.

Figs. 5 and **6** respectively shows the schematic of FSW and specimen prepared. As observed from **Fig. 6** joint prepared at 1500 rpm has some unfilled region at the interface as compared to joint prepared at 2000 rpm. From this observation it is clear that at 1500 rpm frictional heat is not sufficient to generate enough flow ability of material from consumable pin (printed as rapid tooling) to the joint interface. On the other hand joint made at 2000 rpm seems to be better due to more bonding at the interface.

Results and Discussion

Fig. 7 shows sample being tested on universal tensile tester as per ASTM D638. **Table 1** shows observations for mechanical properties and typical stress-strain curve for joints prepared by PEEK (**Fig. 8**). Initially extra flash was removed from the joints by grinding.

As observed from **Table 1** the joints made at 2000 rpm shows more strength as compared to 1500 rpm. Both samples show almost same value of strain. The joint prepared at 2000 rpm did not break from the interface which ascertains that the sound joint was formed. **Table 2** shows the porosity data of weld zone for both the samples. The microscopic observation was taken at 100X zoom level. The level of porosity in the sample prepared at 2000 rpm was 12.64% which is approximately half for sample prepare at 1500 rpm (23.61%). Here high porosity may have resulted into weak mechanical properties. Further Shore D hardness was measured at the joint prepared with two different rpm settings (see **Table 3**). The hardness data was taken from outer weld zone and inner weld zone. Three observations are taken and average of all three reading is coated. As observed from **Table 3**, higher rotational speed results into more hardness. This may be due to fact that at higher rpm more frictional heat is generated and

Table 8 Process capability report for peak strength (MPa)

material get more flowing capability to fill the remaining voids at the weld zone that increase the hardness level and decreases the porosity level. It is also observed that hardness level at inner zone is always lower. This is due to the fact that the flowing material is always tried to move outside from the interfacing zone. So more flowing material automatically come towards outer weld zone and results in more hardness.

Fig. 9 shows the SEM of the fractured zone for sample 1 prepared at 2000 rpm. The fracture mechanism seems to be delamination in tensile testing.

Based upon **Tables 1–3**, 2000 rpm has been selected for joint preparation by FSW. Ten repeated trials were made on 3D printed PEEK substrates. The observations for mechanical and morphological properties are shown in **Table 4**.

Based upon **Table 4**, **Tables 5–9** shows process capability report for (a) Shore D hardness at outer weld zone, (b) Shore D hardness at inner weld zone, (c) Porosity (%), (d) Peak strength (MPa), (e) Break strength (MPa). As observed from **Tables 5–9**, process capability histogram, normal probability plot is well in control and process capability indices Cp and Cpk are ≥ 1 . Hence it is ascertained that the joining process for PEEK with FSW at proposed settings are under statistical control and can be used for batch production.

Futuristic Aspects of PEEK Joining With FSW for Sustainability

The published literature reveals that PEEK has been accepted as useful thermoplastic for bio-medical applications as well as for handling/transportations of low intensity nuclear waste such as gloves used by medical practitioner while chemotherapy (in form of

some containers) (Ajeesh *et al.*, 2015; Miedema and Walker, 2001). Many commercial manufacturers have lunched PEEK containers as a product for these applications. As observed from the mechanical properties achieved in present case study, for maintenance and repair, sealing of charged/filled containers of PEEK (for airtight sealing) the proposed process of FSW can be successfully used. The idea over here is to use PEEK based consumable tool on PEEK substrate in FSW (for minor repair/sealing of the PEEK containers containing nuclear waste for storage applications). This may provide a cost effective, foolproof sealing and repair of PEEK containers as per tailor made requirements leading to better sustainability and repair of existing containers for better re-usability.

Conclusions

The 3D printed PEEK based functional prototypes were successfully joined in the present case study with FSW. Following are the conclusions from the present study:

- (1) The results of study suggest that the joint strength in FSW of 3D printed PEEK was compromised (around 12.9 MPa from 50 MPa of substrate) at the weld zone but the surface hardness observed was of the similar range.
- (2) At outer weld zone even betterment in surface hardness has been observed with controlled porosity level.
- (3) As regards to mechanical and morphological properties, process capability histogram, normal probability plots are well in control and process capability indices Cp and Cpk are ≥ 1 . Hence the joint properties of PEEK with FSW at proposed settings are under statistical control and can be used for batch production.
- (4) Finally the proposed process can be utilized for minor on-line repair of scaffolds/implants in field applications.

Introduction

The journey of the application of cellulose nanofibrils in green composites has dated back over six decades with progressive achievement on the vital role of nanocellulose NC as an important material in industrialization. The roadmap for the emergence of NC in the creation of new bio-economy has witnessed the application of microcrystalline cellulose in food and cosmetics, pharmaceuticals and basic industrial chemicals. Based on the unique properties of these materials, the global market outlook has projected that the annual turnover of NC could reach 808.29 million dollars by 2022 ([Rajinipriya et al., 2018](#)). Recently, there has been global shift from the utilization of Petroleum based polymers composite due to environmental issues, increases in the price of petrochemicals and thinning accessibility of petrochemical resources ([Zia et al., 2016](#)). Other factors include the non biodegradability of their waste materials after their functional life and consequently poor waste management resulting in green gas emission and environmental pollution as a result of poor waste management ([Otegbulu, 2011](#)). This has drawn the attention of the researchers to the exploration of materials that could be reused, recycled or reduced after use in order to mitigate this ugly development. For over three decades now there has been an increasing demand for products made from renewable and sustainable resources that are biodegradable, non-petroleum based, and carry low environmental, animal/human health, and safety risks ([Woldeyohannes et al., 2016](#)).

Basically green composite are formed by the combination of biodegradable polymers like Polysaccharides (Starch, Cellulose, Chitin), Proteins (Collagen/Gelatin Casein or proteins from legumes) of Polyesters with natural biodegradable resins to form natural fibers recyclable green composites. Cellulose has been the most favourable candidate being the most abundance biopolymer on earth, as well as its derivatives have been widely studied as renewable materials. Cellulose which comprises of a linear polysaccharide made up of β -D-anhydroglucopyranose units is abundantly present in wood, cotton, hemp, and other plant-based materials and serves as the dominant reinforcement material in plant structures ([Chiellini and Morelli, 2011](#)). Cellulosic materials such as wood, hemp, cotton, and linen have been used in the area of pharmaceutical, food, biomedical, paper production and engineering construction ([Sundarraj and Ranganathan, 2018](#)). Apart from plant materials, cellulose has been found in some species such as, invertebrates, fungi, tunicates, bacteria algae, amoeba and fungi ([da Silva et al., 2017](#)). The major functional parameters of nanocelluloses produced from difference sources vary in geometrical dimensions depending on the source of the cellulosic material and the hydrolysis conditions with their functional properties are shown in [Table 1](#).

From [Table 1](#) it is shown that the morphological characteristics of the various fibers are studied with the aid of equipment such as Transmission Electron microscopy (TEM). Others include- Atomic force microscope (AFM) Field Emission Scanning Electron Microscopy (FESEM), Small angle neutron scattering (SANS) and both polarized light scattering and depolarized dynamic light scattering (DLS, DDLS). The abundance of cellulosic materials is pivotal to the level and volume of its consumption in agro-based industries such as craft and textiles; paper and particle boards; wood furniture and particle boards etc ([Laftah and Wan Abdul Rahman, 2016](#)).

Nanocellulose NC

Globally, nanocellulose has been gaining increasing interest in the variety areas of application due their excellent mechanical properties, renewability, biocompatibility, good optical properties and biodegradability. It has been found profound application in the field of material science and engineering for food packaging and construction. [Fig. 1](#) is the summarized scheme of area of utmost application of the green nanocellulose.

Recently polymer industrial researchers have found another breakthrough in the extraction and modification of the wood fibers for nanocellulose with one dimension of the material in the nano range. This cellulosic material has been reported as a promising candidate as biodegradable materials ([Khalil et al., 2017](#); [Owolabi et al., 2017](#); [Abdul Khalil et al., 2018a](#)). Cellulose is an assembly of uniaxially ordered fiber naturally built up in hierarchical structured which can be broken down to cellulose nanofibrils. These nanofibrils are made up of firstly longer reaching to several microns in length semi-crystalline elementary fibrils called cellulose nanofibrils (CNFs), and secondly dimensionally smaller and chemically isolated from CNF called cellulose nanocrystals (CNCs). Their properties are adjudged on the basis of their morphology surface chemistry, crystallinity and aspect ratio. Primarily these nanocellulose materials are stimulated by their methods of extraction route ([Saurabh et al., 2016](#)).

Significant increasing research on nanocellulose and nanocellulose-based materials production have been accomplished over the last few decades as a result of their nanoscale dimensions which make them susceptible to modifications. Results from the

literatures have shown that these materials have excellent mechanical properties, biodegradability and nontoxicity (Jorfi and Foster, 2015). Nanocellulose can be extracted from various lignocellulosic biomass sources by means of mechanical, chemical, and enzymatic methods or combination of any of the techniques. Based on the preparation technique used and the appearance of nanocellulose, they are divided into three general groups, namely CNFs, BC, and CNCs. Fig. 1 illustrate the relationship between these different kinds of nanocellulose (Vieira *et al.*, 2011).

Nanocellulose fiber production (NCFs) is natural fiber mainly produced from cellulose via mechanical treatment such as grinding or homogenization. Furthermore, they are flexible fibers with diameter ranging between 20 and 50 nm and the fiber length in 500–2000 nm entangled fibrils that contain both amorphous and crystalline cellulose domains (Mishra *et al.*, 2017). On the other hand, CNCs are produced via acid hydrolysis, which is a chemical treatment process. CNCs are whiskers or needle-shaped and are shorter with length in the range of 100–500 nm and diameter in the range of 3–50 nm (Tan *et al.*, 2015; Abdul Khalil *et al.*, 2018b). The size of the isolated CNFs and CNCs depends on the preparation conditions and source of cellulose. Currently, conventional mechanical and chemical treatment processes, which are traditionally used to prepare CNFs and CNCs are still very well known. Other promising production techniques as well as pretreatment processes have also been proposed in order to develop an economically efficient and eco-friendly production route for nanocellulose (Kargarzadeh *et al.*, 2018).

Mechanism of Nanocellulose Reaction

Broad studies on the application of nano-scaled cellulose have been conducted and reported in various field such as: composite, biomedical, automobile, paper industry, packaging, membranes, food or pharmacy, and construction (Trache *et al.*, 2016). The reactivity of the NC is borne out of the presence of three hydroxyl groups in each anhydroglucose unit. These anhydroglucose unit can react partially or fully with chemicals with improve property characterizations. It was reported that the hydroxyl group at the 6th position acts as a primary alcohol, while the 2nd and 3rd positioned hydroxyl behave as secondary alcohol (Lin and Dufresne, 2014) as shown in Fig. 2.

The reactivity of each anhydroglucose moiety in the polysaccharide is a function of the replaceability of the –OH group which is termed degree of substitution DS in the anhydroglucose unit (Mondal, 2017). Each of the unit can only replace a maximum of three resulting in the DS values ranging from 0 to 3. This phenomenon of degree of substitution promotes the reactivity of the anhydroglucose unit through the intramolecular hydrogen bonds. The intramolecular hydrogen bond occurs between the hydrogen borne by the OH group of the C3 carbon and ring oxygen of the adjacent glucose unit (O5). In addition the

Fig. 1 Relationship between different kinds of nanocelluloses. Adapted with permission from Lin, N., Dufresne, A., 2014. Nanocellulose in biomedicine: Current status and future prospect. *European Polymer Journal* 59, 302–325, Copyright 2014. Reproduced with permission of Elsevier.

intermolecular hydrogen bonds occur between the hydrogen of the OH-6 primary hydroxyl and oxygen in position O3 in a cycle of a neighboring unit, as well as the hydrogen of OH-2 and oxygen in position O6 (De France *et al.*, 2017). The ability of these hydroxyl groups to form hydrogen bonds plays a major role in the formation of fibrillar and semicrystalline packing (Li *et al.*, 2013). Aside the presence of the -OH group, another interesting radical introduced to the surface of the nano sized crystalline particles is the negative sulphide radicals (Xiang *et al.*, 2017). These substances were introduced to the surface of crystalline nano cellulose particle during the sulfuric acid hydrolysis of CNF that leads to the cellulose nanocrystalline CNC synthesis.

Life Cycle Assessment of Green Composite

The term green composites is generally refers to materials prepared by blending biodegradable polymeric substance and other organic or inorganic components. This blending uses conventional plastic processing equipments followed by thermo-molding of the mixture at elevated temperatures to crosslinked the matrix (Van den Heede and De Belie, 2012). As shown in Fig. 3, the philosophy behind the life cycle assessment of green composite is evaluating the synergy of the mutual interaction between green composite manufacture and the environmental reaction.

Fig. 2 Schematic representation of the chemical structure and intra-, inter-molecular hydrogen bonds in crystalline cellulose. Adapted with permission from Lin, N., Dufresne, A., 2014. Nanocellulose in biomedicine: Current status and future prospect. *European Polymer Journal* 59, 302–325, Copyright 2014. Reproduced with permission of Elsevier.

Fig. 3 Life cycle assessment of green composite.

It is pertinent to note that evaluation of ‘green’ nanotechnology is very important especially its impact on the environment requires a full life cycle assessment (Flynn and Traver, 2013). The roadmap to green composite has witnessed the use of natural fibers which is green by the virtue of its biodegradability as reinforcement for plastics, replacing fibers synthetic materials. Life Cycle Assessment (LCA) which was kick started about two decades ago, is now spelled out in the International Organization for Standardization (ISO) 14040 environmental management series standard. The major function of LCA is that, it evaluates every

Fig. 4 Summary of the general method of production of nanocellulose.

environmental impact assessment EIA presented by the manufacture with respect to the application and disposal of their product. The operation of the LCA consists of four major steps: (1) goal and scope definition; (2) inventory analysis; (3) impact assessment and (4) interpretation (Liu and Ramirez, 2017). It has been proposed that industries need to show the life cycle benefits of composites which is the focus of LCA. Fig. 4 presents a typical life cycle of polymer nanocomposite.

Biocompatibility and Toxicology

Cellulose is generally considered as biocompatible due to their ability to blend with living tissues in vivo without causing injurious changes, which is an important prerequisite for biomedical materials (Rosamah *et al.*, 2018). Biocompatibility of CNs have made very easily incorporated into a wide range of polymer matrices, which has also made them very useful in biomedical application because they remain in contact with living tissue without causing any cytotoxic or other side effects as revealed by in vivo animal experiments. Despite the non toxicity of nanocellulose materials, it has been reported that excessive inhalation dosage of the material may trigger pulmonary inflammation because of the self-aggregation and bioaccumulation of cellulose material in the body (Jorfi and Foster, 2015). Many literature reports have attested to the cellulose biocompatibility through various studies. Of all the studies conducted, BC is commonly regarded as a material possessing best biocompatibility. Examples of the recent toxicology reports for different types of cellulose materials are summarized in Table 2. The cellulose- biomaterial interaction has been reported largely influenced by the presence of hydrophobic and hydrophilic sphere of influence. Other factors that are crucial to the cellulose biomaterial interaction include surface charge, wettability, surface chemistry and surface topography. Nanocellulose materials are very versatile and very important as biomedical materials due to their biocompatibility and nontoxicity.

Meanwhile their chemical surfaces functionalization with bioactive molecules is important in biomedical applications for improved interactions with the human body.

Isolation of Cellulose Nanofibrils CNFs

Cellulose nanofibers are extracted from lignocelluloses materials like wood, non wood, agricultural residues like wheat straw, soy hulls etc by a chemi-mechanical technique as summarized in Fig. 4, to examine their potential for use as reinforcement fibers in biocomposite applications. The ability of nanofibrillated cellulose in improving the quality of paper and paper products, etc has led to assiduous and potential research on its unexploited potential and potential means of its generation.

Basically, three main processes are identified with CNF production from cellulosic fibers which include (a) mechanical treatments (e.g., Cryocrushing, High-pressure homogenization, High intensity ultrasonication, homogenization, grinding, and

Table 2 Toxicological evaluation of some cellulose-based materials for biomedical applications

Cellulose type	Toxicology experiment	Results
CNC	Acute lethal test	Low toxicity potential
	Multi-trophic assays	Low environmental risk
	Animal experiments with fathead minnow and Zebrafish reproduction tests	
	In vitro rainbow trout hepatocyte assay	
	Respiratory toxicity of aerosolized CNC on the human airway with a co-culture of human monocyte-derived macrophages, dendritic cells and a bronchial epithelial cell line	Low cytotoxicity Somewhat (pro-)inflammatory cytokines
	In vitro gene mutations	No evidence of high toxicity
	In vitro and in vivo chromosomal tests	
	Skin irritation and sensitization tests	
	Animal experiments with rat feeding study (28 d)	
	Cytotoxicity evaluation with L929 cells	Low cytotoxicity at low CNC concentration
CNF	Cytotoxicity evaluation with nine different cell lines	No cytotoxic effects in the concentration range (0–50 lg/mL) and exposure time (48 h)
	Cytotoxicity evaluation with human monocyte and mouse macrophages	No evidence of inflammatory effects or cytotoxicity
	Kinetic luminescent bacteria test for acute environmental toxicity	
	In vitro genotoxicity with enzyme comet assay	No significant DNA damage
	Neurotoxicity and systemic effects with a nematode model	Low or no cytotoxicity
	In vitro pharyngeal aspiration study for pulmonary immunotoxicity and genotoxicity with mice	No DNA and chromosome damage
		Pulmonary inflammation
	Cytotoxicity evaluation with 3T3 fibroblast cells (including the test of cell membrane, cell mitochondrial activity and DNA proliferation)	No toxic phenomena for pure CNF Somewhat cytotoxicity for modified-CNF (with PEI or CTAB surface modification)
	Cytotoxicity evaluation with bovine fibroblasts cells	Low cytotoxicity at low CNF concentration (0.02–100 lg/mL)
	Effects of gene expression in vitro	Reduction of cell viability and affection of the expression of stress- and apoptosis-associated molecular markers at high CNF concentration (2000–5000 lg/mL)
BC	Cytotoxicity evaluation with human dermal fibroblasts	No evidence of cytotoxicity for pure CNF Improved cytocompatibility of EPTMAC-modified CNF
	Cytotoxicity evaluation with osteoblast cells and L929 fibroblast cells	No evidence of cytotoxicity
	Cytotoxicity evaluation with human umbilical vein endothelial cells	
	Animal experiment with C57/Bl6 male mouse	No evidence of toxicity in vitro and in vivo
	In vitro immunoreactivity with human umbilical vein endothelial cells	Non-toxicity and non-immunogenicity
	In vivo intraperitoneal injection study with BALB/c male mice	

Abbreviations: PEI, polyethyleneimine; CTAB, cetyl trimethylammonium bromide; EPTMAC, glycidyltrimethylammonium chloride.

milling), (b) chemical treatments (e.g., TEMPO oxidation), and (c) combination of chemical and mechanical treatments simple mechanical shear, refining or by a combination of chemimechanical milieu (Shaghaleh *et al.*, 2018). It has been reported in the literature that CNF has been isolated and characterized from variety of lignocelluloses sources using different methods (Kargarzadeh *et al.*, 2018; Shaghaleh *et al.*, 2018; Owolabi *et al.*, 2016). Below is a short appraisal of some of the widely reported preparation protocols for CNF materials.

Cryocrushing

This is a method to produce cellulose nanofibrils through the combine action of rigorous shearing in a refiner prior to high-impact crushing under liquid nitrogen (Chakraborty *et al.*, 2005). The mechanism of this process involves action of high impact forces the fibers frozen under liquid nitrogen followed by high pressure fibrillation. This method of CNF production has successfully been used to prepare CNF from soybean stock (Torregrosa *et al.*, 2016), from wheat straw and soy hull (Alemдар and Sain, 2008). While wang and Sain (Wang *et al.*, 2007) reported the resultant fibers were 50–100 nm in diameter, Alemдар and Sain (2008) reported that the diameter of the extracted nanofiber was in the range of 10–80 nm with length on the order of a few thousand nanometers. The studies characterized the CNF with respect to the physical and thermal properties of the nanofibers with the aim of assessing their feasibility in biocomposite applications.

High-Pressure Homogenization (HPH)

This is a type of CNF production by mechanical means. Large scale production of CNF has been achieved through the use of High-pressure homogenization (HPH) (Wang *et al.*, 2017). This mechanical technique utilizes variety of forces for size reduction of natural cellulose leading to nanoscale cellulose. Most high-pressure homogenizers use a combination of forces – most commonly cavitations and impact, which is homogenizers and microfluidizers (Mishra *et al.*, 2017). The perception of the “homogenization” refers to the ability of producing a homogeneous size distribution of particles in a liquid suspension. Conventionally HPH delivers pressure and flow based on a constant volume method and variable homogenizing valve configurations, which commonly yields very large process pressure variations during each pumping cycle (Owolabi *et al.*, 2017; Orsuwan and Sothornvit, 2018). The higher the pressure, the higher would be the disruption efficiency per pass through the equipment. The resulting particle size is usually large with a broad size distribution. Consequence to intensifier pump and fixed geometry orifice, uniform shear with small particles distributions is achievable by microfluidizer (Tang *et al.*, 2001). Herrick *et al.* (1983) and Saarikoski *et al.* (2015) first reported this mechanical technique of CNF production with homogenizer and large pressure. Consequently Li *et al.* (2014) reported the extraction CNFs from depectinated sugar beet pulp through the combination of chemical treatment with HPH while Chen *et al.* (2014) also reported the CNF production from raw dried cotton fibers. The diameter of the resultant CNFs ranged from several nanometers to 70 nm and it was shown that the crystallinity of the nanofibers increased significantly after treatment.

On the issue of the thermal effect, the majority portion of the mechanical energy applied to any system will eventually be dissipated into the form of heat. HPH usually causes the excessive temperature increase in the processed materials. Although it depends on the setup and what the mechanisms are within the system to mitigate heat buildup. Microfluidized materials will only have moderate temperature increment, which makes it ideal for applications with heat sensitive materials (Jana *et al.*, 2017). Generally this method has been reported as the most expensive method for the nanomaterial isolation.

Refining Process

CNF production with improved functional characteristics has been saddled with a lot of challenges due to the growing demand in the fields of medicine, food and cosmetic and packaging industries. The process involving the passage of cellulose through a gap in between two ridged discs is called grinding process. In this case, cellulose fibers are enforced through two wavy discs one of which is static and the other revolving at about 1500 rpm. Delamination of the cell wall occurred through the process by the high shear forces, resulting in the production of individual nanosized fibers. The extent of fibrillation depends on the distance between the discs, morphology of the disc channels, and number of cellulose fibers that passed through the grinder. It was reported that application of the grinding method on wet wood fiber resulted in 15 nm diameter of CNF (Abe *et al.*, 2007), which give the efficiency the application of this method in nanofiber production. This result was similar to the report of Iwamoto and coworkers (Iwamoto *et al.*, 2005) after the application of the grinding method on cellulosic pulp resulted in CNF of 50–100 nm diameter.

High Intensity Ultrasonication

This is a chemimechanical technique involving the combine chemical pretreatment and high-intensity mechanical ultrasonication (Chen *et al.*, 2011). In this milieu, the introduced cellulose fibers are steadily disintegrated into nanosize due to the impact of ultrasonic waves. The process involves the chemical delignification of the plant fibers by either mild acid hydrolysis, or alkali treatment prior to bleaching process to remove non-cellulosic materials such as hemicelluloses and lignin. Prior to the ultrasonication process, the chemical pretreated cellulose fibers are thoroughly washed and soaked in distilled water (Nurul Fazita *et al.*, 2016).

Steam Explosion Process

This is another process of CNF extraction involving explosive decompression prior to the use of vapor phase short cooking duration at 180–210°C vapor phase cooking for a short duration at a temperature in the range of 180–210°C, followed by explosive decompression and sudden release of pressure (Stelte, 2013). The lignocelluloses biomass to be used for this protocol are subjected to short time pressure in a steam autoclave followed by explosively ejection to the atmospheric pressure leading to rapid breakup of the lignocelluloses material into a fibrous detached solid fibers. On the long run this process results in significant breakdown of the lignocelluloses division dissolution of the lignin structures and the separations of the fiber materials. The application of this technique has been widely reported in the literature. According to the literature, steam explosion process has been used for the extraction of cellulose nanofibers from pineapple leaf fibers (Cherian *et al.*, 2010), banana plant (Deepa *et al.*, 2011), isora fiber (Chirayil *et al.*, 2014) etc.

Electrospinning

Electrospinning is a simple method of NFC production with a solvent or chemical derivatization of cellulose. This method was formulated as a result of the difficulty experienced during direct dissolution of cellulose (Bhardwaj and Kundu, 2010). This nanofiber solution process of production has been adjudged very simple since it uses electrospinning under the action of a high electric field and economical because once the voltage is sufficiently high, a charged stream of matter is ejected following a rather complicated loop. During this process, the solvent evaporates leaving behind randomly oriented nanofibers that accumulate on the collector (Sun *et al.*, 2014). CNFs production

through electrospinning technique has been reported in the literature. According to [Ma et al. \(2014\)](#), cellulose acetate (CA) nanofibers was prepared by the electrospinning technique with an acetone/dimethyl formamide (DMF)/trifluoroethylene (3:1:1) mixture as the solvent. The result showed that the diameter of the produced nanofiber ranged from 200 nm to 1 μ m.

Cellulose Nanocrystals (CNC) Production

CNCs are produced via acid hydrolysis of the nanofibrillated cellulose through chemical treatment process or from naturally occurring cellulose sourced from cotton, variety of wood pulp from different protocols, bacteria cellulose and tunicates. CNCs are whiskers or needle-shaped and are shorter with length in the range of 100–500 nm and diameter in the range of 3–50 nm ([Kallel et al., 2016](#)). The size of the isolated CNCs like the CNFs depends on the preparation conditions and source of cellulose. Besides the conventional mechanical and chemical treatment processes, which are traditionally used to prepare CNFs and CNCs, other promising production techniques as well as pretreatment processes have also been proposed in order to develop an economically efficient and eco-friendly production route for nanocellulose ([Chen et al., 2015](#)). The general method commonly used for the production of cellulose nanocrystal CNC is either hydrochloric or sulfuric acid hydrolysis with heat controlled techniques followed by centrifugation/redispersion and dialysis until neutral pH is obtained. One of the unique characteristics of sulfuric acid hydrolysis is the attachment of negatively charged sulfate half-ester groups onto the surface of the particles, which impose electrostatic repulsion between fibers particles preventing aggregation of the nanocellulose crystals in aqueous suspensions. Additionally, the rod-like shape of CNCs leads to concentration-dependent liquid crystalline self-assembly behavior with near-perfect crystallinity of about 90% ([Reid et al., 2016](#)).

Bacteria Cellulose (BC)

BC is also known as cellulose nanowhiskers (CNW) or bacterial nanocellulose is characterized by high purity, strength, moldability and increased water holding ability. It is produced extracellularly by microorganisms like bacteria of which *G. xylinum* is the most famous of them mainly to form protective envelopes around their cells ([Huang et al., 2014](#)). Unlike the plant sourced nanocellulose, BC is synthesized as pure natural cellulose with average fiber diameter of 20–100 nm and several micrometer lengths. microbial cellulose is more chemically pure, containing no hemicellulose or lignin, has a higher water holding capacity and hydrophilicity, greater tensile strength resulting from a larger amount of polymerization, ultrafine network architecture ([Stumpf et al., 2018](#)). Furthermore, bacterial cellulose can be produced on a variety of substrates and can be grown to virtually any shape due to the high moldability during formation. Additionally, bacterial cellulose has a more crystalline structure compared to plant cellulose and forms characteristic ribbon-like microfibrils. A hallmark of microbial cellulose, these thin microfibrils are significantly smaller than those in plant cellulose, making bacterial cellulose much more porous ([de Oliveira Barud et al., 2016](#)).

Challenges of Nanocellulose Application

Despite the wide acceptability of nanocellulose in various field of manufacturing, nanocellulose in spite of their versatility nanocellulose fibers still show some properties that limit their applications. One of the challenges in the use of nanocellulose is compatibility with the polymer matrix in composite development ([Jorfi and Foster, 2015](#)). This is attributable to the hydrophobic nature of the polymer matrix as against the nanocellulose that are majorly hydrophilic fibers which result in non-uniform dispersion of fibers within the matrix hence poor mechanical properties. In order to have a good blend the projection on the nature of the molecular structure and the proposed interfacial interaction expected between the matrix and the nanocellulose fibers is of great importance in polymer composing. The main aim of green composite development is the enhancement of the mechanical properties which tend to be compromised in some cases. Most biopolymers employed for this purpose like Chitosan ([Serpa et al., 2016](#)), cellulose and gelatin are not readily available hence involves laborious efforts to be extracted. It has been reported that the use of starch nanoparticles tends to compromise the mechanical properties hence lead to the use of plasticizer unlike poly lactic acid (PLA). However, PLA used in green nanocomposite has been reported characteristic thermally low glass transition temperature and weak thermal stability. Green nano composite suffers the problem of dispersion of the biopolymers in the polymer composite ([Ng et al., 2017](#)). In some cases specialized equipment like high sonication is needed to enhance adequate spread of the nanocellulose fillers. The mechanical properties of the green nanocomposite also depend on the fiber orientation which is pretty difficult to achieve with nanoparticles unlike the micro cellulose counter-part. Apart from the above methods at overcoming the challenges of filler/matrix adhesion in green nanocomposite, efforts such as fiber surface modification, addition of compatibilizers and also matrix mercerization have been reported ([Haafiz et al., 2017](#)). To overcome the challenges of compatibility and grafting between fibers and thermoplastic matrices in green composites production, surface treatment by the use of additives is adopted. The common additives used include chemical coupling agents or compatibilizers Maleated polyethylene (MAPE) ([Sundrababu and Griskevicius, 2018](#)), carboxylated polyethylene (CAPE) ([Li et al., 2012](#)), titanium derived mixture (TDM), Maleic anhydride polypropylene (MAPP), ([Benhamou et al., 2015](#)), calendaring, stretching ([Jonoobi et al., 2015](#)), thermo treatment ([Effah et al., 2018](#)), reaction with methanolmelamine, isocyanates, triazine, silane ([Ashik et al., 2017](#)) and mercerization of the matrix ([Liu et al., 2015](#)). Despite all these possibilities, a better understanding of the molecular structure and interfacial

interaction between the matrix and the fibers and the relationship between the structure and property is very important in this area of research (Adeosun *et al.*, 2012).

Recent Advances in Green Nanocomposite Research

Green nanocomposites are gradually gaining wide acceptance in the mainstream of global industrial landscape like biomedical, construction, packaging, and plastics processing. The production of these nanocomposite materials with particles measuring tenths of a nanometer has almost revolutionized the plastics industry with respect to its production and applications (Rosamah *et al.*, 2018). Nanocelluloses which are nano-structured cellulose (CNC or NCC, CNF) have been reported use nanotechnology through hydrogel or aerogel in which the liquid component for the gel has been replaced with a gas for water purification. As a result of their biodegradability, excellent thermal and mechanical properties couple with low density and high aspect ratio, CNCs stand the potential candidate to replace the toxic or non-biodegradable materials mostly in the composite industry. Although one of the main challenges restraining the usage of CNCs in polymer biocomposite is hydrophilicity which is being addressed by altering its surface chemistry to improve its compatibility with hydrophobic matrices. As a result of the excellent properties and eco-friendliness of the nanocellulose it has attracted wide research applications in fields like in the manufacture of green nanocomposite materials, material surface modification, and functional transparent paper. Therefore nanocellulose (CNF, CNC or BC) applications in green nanocomposites have been recently reported as they are better and potential candidate to provide a positive environmental impact and remarkable characteristics. The summary of the recent research efforts in the area of nanocellulose applications is summarized in Table 3.

Table 3 Summary of recent advances in nanocellulose-thermoplastic composites

Nanocellulose type	Polymer component	Manufacturing technique	Applications
CNCs	Methylcellulose	Hydrogel by aqueous dispersion	Thermoreversible and tunable nanocellulose based hydrogels
	Plasticized starch	Solution casting	Transparent materials
	Starch blending	solution casting	Air permeable, resistant, surface, sized paper, food packaging
	PVA	Solution casting	Stretchable photonic devices, conductive materials
	Plasticized PLA	Twin screw extruder	Film blowing, packaging Wound diagnosis/ biosensor scaffolds
	Maleic anhydride grafted PLA	Electrospinning	Bone tissue engineering
	Cellulose esterified with lauroyl chloride	Solution casting and thermopressing	Interface melting
	PC	Matsterbatch melt extrusion process	Optical devices
	PC based polyurethane blend	Solution casting	Smart actuators and sensors
	Ethylene-co-vinyl acetate rubber	Solution mixing and vulcanization	Transparent, rubbery materials
CNFs	PU	Solution casting	High temperature biomedical devices
	Polyethylene glycol	PEG-g-CNF ribbons by stretching hydrogel	Ultra-high tensile strength and modulus for optoelectronic and medical devices
	Amorphous dialcohol cellulose	Oxidation + reduction of CNF	Surface Barrier films
	Polyethylene	Extrusion	High performance cellulose, environmentally friendly HDPE
	Thermoplastic starch	Solution Casting	Evaluation of cotton filler in LDPE
	Maize amylopectin	Solution casting	thermally stable starch
	Polyvinyl amine	Layer by layer	Continuous papermaking
	Polyacrylamide	Solution casting	Self healing polymer films
	PVA	Solution casting	Films with good mechanical, optical thermal and oxygen barrier properties
	Carboxymethyl cellulose	Solution casting	Flexible displays, optical devices, packaging and automobile windows, Food packaging
BC	Poly(butylene adipate-co-terephthalate)	Injection molding	Edible coatings and packaging materials
	Poly(ethylene oxide) based block copolymer	Solution casting	Light-weight and high performance materials for defense, infrastructure and energy
	PMMA	Solution casting	Transparent biocomposites
CNFs, CNCs, BC		Solution casting	Packaging, flexible screens, optically transparent films and light, weight materials for ballistic protection

Prospect of Green Nanocomposite

The current progressive milestone recorded in the area of green revolution in bio-composite from natural fiber with respect to environmental friendliness, has instigated further research and development of potential application of nanocellulose in green composite. This has heralded a lot of breakthroughs in this design with numerous applications. Irrespective of the reported limitations with respect to the hydrophilicity of the nanocellulose in green nanocomposite research and development and has rendered the attention on the use of petrochemical based composites unappealing due to a few challenges that bother on environmental and community pollution, waste management such as disposal, reusability and recycling problems (Abdul Khalil *et al.*, 2012). **Table 4** gives a summary some of the activities carried out under the green nanocomposite study.

The large concentration of hydroxyl groups on the surface of the nanocellulose enhances their high hydrophilic properties as a result of their enlarged surface area which enables their use as rheology modifiers mainly in paints and personal care products. Preparations of nanocellulose based hydrophobic aerogels produced from various agricultural wastes have been reported, and results showed the great tendency towards their use in water body purification. Apart from the above mentioned, green nanocomposite material is pivotal on some vital properties such as light weight low density and high mechanical properties. Nanocomposites have been used in several applications in automotive industries such as various vehicle types of door handles, door panels, instrument panels, parcel shelves, head rests, roofs, upholstery and engine covers and intake manifolds and timing belt covers. The use of green nanocomposite in impellers and blades for vacuum cleaners, power tool housings, mower hoods and covers for portable electronic equipment such as mobile phones, etc are receiving interesting attentions (Garate *et al.*, 2018). As long as the consumption of these materials continues to increase, there is bound to be new discoveries for the use of green nanocomposite. The intrinsic properties of nanocellulose which include low density with high aspect ratios facilitate the application of Nano Cellulose in green composites for the fabrication of lightweight and high performance materials. Despite the various research reports on potential and progress made in the application of green nano composite especially in the area of improvement of its commercial potential, sustainable environment should be created to compete with petroleum-based plastics, economically. Another area of paramount importance is in the area of providing cheap and affordable technology proficiency to produce the green nano composite. **Fig. 5** summarizes some prospective industrial application of nanocellulose for green nanocomposite.

The large concentration of hydroxyl groups on the surface of the nanocellulose enhances their high hydrophilic properties as a result of their enlarged surface area which enables their use as rheology modifiers mainly in paints and personal care products. Preparations of nanocellulose based hydrophobic aerogels produced from various agricultural wastes have been reported, and results showed the great tendency towards their use in water body purification.

They have been widely used as reinforcement filler in the field of nanocomposites with improved barrier and mechanical properties of dry green composites and also enhance biodegradability of the prepared green composite. Various research finding

have reported the excellent mechanical strength enhancement of the nanocomposite addition in polymer matrix. According to the literature reports, nanocellulose extracted of soyabean gave significant improvement in the mechanical properties when used to reinforce synthetic polymers (Abdul Khalil *et al.*, 2014). When used to reinforce polylactic acid, nanocellulose was discovered to enhance the mechanical properties of the composite formed (Aulin *et al.*, 2013). Green polymers so far used for the preparation of nanocomposites include chitosan (Kumar, 2018).

Conclusions

The recent attention on the use of biodegradable polymer in various industries due to economic and environmental consideration have given rise to the interest in green nanocomposite which has gained wide range of applications in food packaging, fibers, automobile, hydrogels, or aerogel biomedical, transparent films, and agriculture fields. In green composite and sustainable materials, nanocellulosic materials have played significant role based on their fundamental intrinsic properties. Consequently, the previous milestone of achievement on the applications of nanocellulose (CNCs, CNFs, and BC) in various fields of manufacturing has not been exhaustively researched based on sources and applications. They are considered better replacements for petroleum-based products in terms of ecology and economical issues. There are still possibilities of more discoveries based on the abundance of the array of sources which may no longer be of concern but the cost of production. It is obvious that there is abundant window of opportunities for unraveling the potentials in nanocellulose as potential candidate for solving more problems in the industries

and assist researchers in tackling more imminent challenges in the field. Plant sourced nanocellulose has been shown to have unique characteristics such as high crystallinity, aspect ratio, Young's moduli, and tensile strengths, which originate from the properties of natural wood cellulose microfibrils. The ubiquitous cellulose with unique flexible properties to replace the synthetic and petrol chemical materials is of particular interest for the future application.

Part 1 – Background

Historical Usage of Kenaf

Kenaf (*Hibiscus cannabinus* L., Malvaceae) is a warm season yearly fiber crop closely associated with cotton (*Gossypium hirsutum* L., Malvaceae) and okra (*Abelmoschus esculentus* L., Malvaceae), which can be grown effectively in a big part of the field. The commercial use of kenaf continues to diversify from its historical usage as a cordage crop (rope, string, and sackcloth) to its various new applications, including paper products, construction materials, absorbents, and livestock feed.

Kenaf has been utilized as a cordage crop to create twine, rope, and sackcloth for more than six centuries (Dempsey, 1975). Kenaf was first trained and utilized in Northern Africa. India has delivered and utilized kenaf throughout the previous 200 years, while Russia began creating a war in 1902 and introduced the product to China in 1935. In the United States, kenaf research and creation started amid World War II to supply cordage material for the war effort (Wilson, 1965). The war did not just intrude on the remote fiber supplies from nations like the Philippines. However, the US inclusion in the war had additionally expanded the utilization of these strands by the US. It was resolved that kenaf was a reasonable harvest for US use, so an experiment was initiated to augment US kenaf yields. Subsequently, researchers successfully grew high-yielding anthracnose-safe cultivars, instituting social practices and gathering apparatus that expanded the fiber yields (Nieschlag, 1960; Wilson, 1965; White *et al.*, 1970). At that point during the 1950s and mid-1960s, as USDA specialists were assessing different plant species to satisfy future fiber requests in the US, it was resolved that kenaf was a superb cellulose fiber hotspot for an expansive scope of paper items (newsprint, bond paper, and layered liner board). It was additionally confirmed that pulping kenaf required less vitality and concoction contributions for preparing than standard wood sources (Chark, 1962). Later, innovative work during the 1990s showed the plant's appropriateness for use in building materials (particle sheets of different densities, thickness, with flame and insect resistance), adsorbents, materials, animal feed, and filaments in new and reused plastics (infused, shaped, and expelled) (Webber and Bledsoe, 1993) (Fig. 1).

Harvesting and Processing

The assessment of strategies for harvesting kenaf keeps on being a critical part in commercialization. The harvesting technique relies on the production area, the gear accessibility, processing strategy, and utilization of the final product.

Fig. 1 Plant components. (a) Leaves and plants of kenaf. (b) Kenaf flower. (c) Kenaf stalks at harvest, 150 days after planting. (d) Kenaf seed. From Webber III, C.L., Bledsoe, V.K., Bledsoe, R.E., 2002. Kenaf harvesting and processing. In: Janick, J., Whipkey, A. (Eds.), Trends in New Crops and New Uses, vol. 9. Alexandria, VA: ASHS Press, pp. 340–347.

Harvesting

Hand harvesting and retting for cordage fiber

Over the last 6000 years, since its first domestication, kenaf has systematically been hand-harvested to be used as a cordage crop (rope, twine, and sackcloth) (Dempsey, 1975). The bast strands, settled within the kenaf bark, are the supply for these cordage products. Once hand-harvested, the tall, cylindrical-shaped stalks were cut at or close to ground level with an arched blade or knife. The hand-harvested plants were then ready for the retting method. Retting is a method that sometimes involves moisture with bacteria or chemicals, to get rid of the unwanted bark material from the kenaf fiber strands among the bark. Kenaf was retted by natural processes that use primarily aerobic (air loving) bacteria, unlike water-retting of flax that is carried primarily by an anaerobic bacteria and varied fungi. The entire stalk kenaf (bark and core still attached), or solely the bark parts, are tied in bundles and placed in pond canals, or slow-moving streams to permit the bacteria to digest the material around the bark's fiber strands (bast fibers).

The plant material status before retting influences the water-retting potency for kenaf. Removing the higher, nonfibrous portion of the plant before the retting method will increase the retting rate by decreasing the quantity of leaf and material to be digestible. Whether or not the higher portion of the plant is removed, the setting method will be redoubled if the plants are allowed to dry for 24–48 h after harvesting to enhance defoliation. Removal of the bark from the stalk conjointly makes the retting method more economical. Once drying has occurred, the bark will adhere more aggressively to the stalk core and bast fibers will also be more difficult to separate from the nonfibrous material in the bark. In addition, drying the bark while either attached to or separated from the stalk will impede the water-retting process. Though the natural water-retting (bacterial) method remains to be used throughout several parts of the world, newer chemical retting processes were studied, developed, and enforced to supply fibers of superior chemical and physical uniformity (Dempsey, 1975; Ramaswamy, 1999). The analysis determined that hand-stripped green bark ribbons and automatically separated bark material could be effective with chemicals retted by using 7% and 1% sodium hydroxide, respectively, to produce decent textile quality fibers from kenaf.

Processing

Early processing methods and equipment will be dependent on several factors, such as the assembly location, equipment accessibility, the economic variables concerned, and the available industrial markets. One of the primary process selections is whether the whole stalk, either as an unmodified stalk or as a chopped stalk, will be separated into its bast and fiber components or left unseparated for use as a combined fiber source. Many existing industrial kenaf facilities automatically separate the two fiber elements by totally different ways with distinct process efficiencies, employing a variety of equipment with variable rates of outturn, leading to variable degree of fiber separations. Every separation system conjointly has distinctive economic ramifications that support its integrated production, harvesting, processing, and utilization systems. One methodology of fiber separation adapts unused machine facilities that are scattered throughout the southern region of the United States to process the kenaf fibers. The improved equipment and facilities give outstanding machinery for separating the kenaf core material from the bast fibers, exactly like the strategy used by the cotton gin method to separate oilseed from the cotton fibers. Since the amount of active machine facilities is decreasing with the decline in cotton production, unused gin facilities are obtainable for changing to kenaf separation facilities.

Kenaf Fiber in Technical Applications: Market and Trends

Kenaf (*H. cannabinus* L.) is a plant very similar to jute, and in production statistics, it is usually confused with jute. Moreover, another example of the polysemic use of the word *hemp*, kenaf is usually called “ambary hemp.” According to world production of kenaf and allied fibers was around 340,000 t in 2007/08, down from 430,000 t in 2002/03. The largest 2007/08 producers were India (140,000t), followed by China (87,000t) and Thailand (36,000t), and in all three countries, kenaf is on the decline. According to news reports, kenaf may experience a renaissance nevertheless, specifically in technical applications (Adnan, 2010; Shimbun, 2003), as there is a selected downside with jute for an exposed use, for instance within automotive interiors, which makes kenaf a perfect substitute. To make the jute fibers more elastic and softer, which improves the carding and spinning process, they are usually pretreated with a mineral oil-based so-called jute batching oil, which has a lot of potential for migration, ends up with an oily or fishy smell, and was reported to be carcinogenic (Mehrotra et al., 1988).

Part 2 – Kenaf Fiber Composites in The Automotive Industry

Recently, natural fibers have become more attractive in the automotive industry as an alternative reinforcement for glass fiber reinforced plastics. Furthermore, natural fiber components in the automotive industry can provide many advantages as compared with conventional fibers, such as reduction of weight and price, recyclability, renewability, and eco-efficiency. Therefore, the employment of natural fibers within the automotive industry has shown progressively rigorous environmental criteria (Hassan et al., 2017). Besides, amongst classified bast fibers, such as flax, hemp, jute, ramie, and kenaf, kenaf fiber is seen as a potential natural fiber with sturdy mechanical properties. Kenaf fiber had been explored to enhance desired mechanical properties as automotive structural elements.

Automotive production rate has improved and it has been predicted that 76 million cars will be produced annually by 2020. For that purpose, utilization of biocomposites will lead to major reduction in the weight of vehicles and emissions. And yet, it is estimated that a 25% reduction in automobile weight would correspondingly save 250 million barrels of crude oil (Ranjan *et al.*, 2013). Because of this significance, the automotive industry is meeting these challenges by improving recyclability of recently created and manufactured bio-based products that use domestic natural resources, particularly for the body of cars to achieve weight reduction (Alves *et al.*, 2011; Chen *et al.*, 2005; Jeyanthi *et al.*, 2012). For example, natural fiber composites with thermoplastic and thermoset matrices were embraced by European automobile manufacturers and suppliers for door panels, seat backs, headliners, package trays, dashboards, and interior elements (Holbery and Houston, 2006). Natural fiber reinforced composites are primarily used as low-cost materials that have been utilized in applications like automotive interior linings (Fiore *et al.*, 2015).

Natural fibers have gained revived interest, particularly as a glass fiber substitute in the automotive industry (Mohanty *et al.*, 2005). Commonly, natural fibers may be classified into animal, plant, and mineral sources. Among the three kinds of classification, the natural plant fiber has a lot of potential. According to the plant class, the fibers are extracted, such as bast, leaf, seed, wood, fruit, and straw. Among these, bast fibers have low density and better mechanical properties, thus the opportunity for reinforcements in lightweight composite for automotive parts (Salit, 2014). Bast fibers are derived from flax, hemp, jute, ramie, and kenaf. They provide automobile part reinforcement, owing to such drivers as reductions in weight, cost, and eco-friendliness (Holbery and Houston, 2006). Once an eco-design is taken into account, environmental data with mechanical behavior is progressively being requested too.

A significant current advancement in this field has been the presence of biocomposites, which combine good mechanical performance and low environmental impact (Le Duigou *et al.*, 2014). Due to the attention on environmentally friendly material, natural fiber reinforced polymer composites have increased excellent attention and interest among material scientists and engineers for their mechanical properties and potential contributions (Azwa *et al.*, 2013). They are renewable, cheap, totally or partly recyclable, and biodegradable. They are materials with highly specific strength and modulus, low prices, recyclable, and effortlessly obtainable in some countries (Azlan and David, 2011). Amongst the stated fibers, kenaf (*H. cannabinus* L. family Malvaceae) is one of the strong and stiff agro-based fibers and has adequate potential to reinforce polymers.

Due to the light weight of kenaf fiber composites, the fuel consumption and emission are improved, particularly in the automotive industry. Table 1 shows the dimensions of kenaf fibers for the outer part (bast fiber) and the inner part (core fiber). Each element showed improved mechanical properties even with a different dimension. Comparing with different kinds of plant fiber, kenaf fiber has more potential because both parts of kenaf, bast and core, give good mechanical performance. It is different with other fibers, where only the outer part gives good performance and some fibers only have an inner part that can be used. Considering these advantages, kenaf tends to be grown as another potential natural fiber that can be a substitute for glass fiber within the automotive industry.

Table 2 displays the comparative properties of density, strength, modulus, and elongation at break between kenaf fiber and glass fiber. Glass fiber presents a dominant value for each property, and is widely applied in automotive components. However, kenaf fiber has some advantages over glass fiber in terms of cost, density, renewability, recyclability, abrasiveness, and biodegradability. Improvement in composite properties depends on the fiber-matrix interface, and this contributes to transfer stress from the matrix to the fiber.

Table 1 Fiber dimensions of kenaf fiber

Properties	Bast fiber	Core fiber
Length (mm)	2.32	0.74
Diameter (μm)	21.9 ± 4.6	22.2 ± 4.5
Lumen diameter (μm)	11.9 ± 3.4	13.2 ± 3.6
Cell wall thickness (μm)	4.2 ± 0.8	4.3 ± 0.7

Table 2 Comparison properties of kenaf and glass fiber

Properties	Kenaf fiber	Glass fiber
Density (g/cm^3)	1.4	2.5
Strength (MPa)	284–800	2000–3000
Modulus (GPa)	21–60	70
Elongation at break (%)	1.6	2.5

Source: Jeyanthi, S., Jeevamalar, J., Jancirani, J., 2012. Influence of natural fibers in recycling of thermoplastics for automotive components. In: *Proceedings of the International Conference on Advances in Engineering, Science and Management (ICAESM)*, pp. 211–214. Institute of Electrical and Electronics Engineers.

The use of natural fiber reinforcement in the automotive industry proves that it is viable in a number of automotive components. Currently, flax, sisal, and hemp are processed into door protective covering, seatback linings, and floor panels (Holbery and Houston, 2006). Prior to this, proper material selection of natural fibers and careful design ought to be carried out so as to attain a better impact behavior, particularly for core structures like the bumper beam for absorbing energy in a crash (Jeyanthi *et al.*, 2012). Numerous recognized compositions of kenaf fiber with matrix and some additives can meet the automotive industry's needs for interior and exterior components as long as they are for nonstructural and semistructural applications. From Table 3, twisted kenaf fiber (Jeyanthi *et al.*, 2012) presented the performance of beams improved with hybrid kenaf/glass reinforced material. This proved that it could be employed in automotive structural components. A twisted kenaf hybrid material could be improved by optimizing the structural parameters, such as thickness, beam curvature, and strengthening ribs. Their applications in automotive components are as bumper beams and front-end modules.

Furthermore, it is a fact that "going green" does not have to cost more. Kenaf-based auto components do not solely prove to be superior with product performance but are also saving auto companies money. Natural fiber-reinforced plastics, vegetable oil-based polyols and polyamides, bio-based polyesters, and thermoplastic elastomers are some of the bio-based materials incorporated in numerous vehicles. A DEFRA report from 2012 projected the expansion rates for biofibers in automotive components at 54% per annum. European automakers have, within the last decade, welcomed biofiber reinforced polymer composites for door panels, seat backs, package trays, dashboards, and trunk liners. In recent years, biofiber composites have become widely acceptable in North America, where virtually 1.5 million vehicles are comprised of applications for biofibers such as kenaf, jute, flax, hemp, and sisal in combination with thermoplastic polymers, such as polypropylene and polyester. The employment of kenaf is anticipated to offset 800,000 pounds of oil-based resin per year in North America alone. The employment of this eco-friendly material reduces the weight of the door bolsters by 25%. Weight savings translate into fuel savings for drivers (Fig. 2).

Besides that, the international automotive industries have been under pressure due to environmental problems, where various regulations were introduced for the sake of environmental protection. One of the problems is recycling automotive interior elements, which has become tough because most petrol-based polymer materials are mixed with composite structures. Current disposal approaches for these auto interior elements are either garbage dumps or burning, both causing environmental concerns (Yan *et al.*, 2005). Due to environmental problems, the replacement with biodegradable material like natural fiber

Table 3 Kenaf fiber composition

Composition	Findings
Twisted kenaf fiber LFRT (TKLFRT) and LFRT	Performance of beams increased
Kenaf with PFA poly(furfuryl alcohol) bio-resin	Good damping behavior
Kenaf and ramie nonwoven fiber with binder: PVA and acrylic copolymer	Enhance the performance of composite thermal and mechanical properties
Kenaf with PLA	Good esthetics and strength

reinforced composite is more preferable. At present, the use of natural fiber reinforced plastics for interior parts can be classified as low. Kenaf bast fiber is recognized to have the potential as a reinforcing fiber in plastic composites. This is often due to its superior toughness and high aspect ratio as compared to other fibers (Akil *et al.*, 2011). The utilization of kenaf fibers reinforced plastics for interior parts requires major technical attention before it is accepted as a substitute for the existing material. Most interior elements need a high standard of mechanical performance, however, it is difficult to find an ideal material that can fulfill the requirements (Nick *et al.*, 2002).

Overall, to enhance the mechanical performance of kenaf fibers as reinforcement material, it is essential to alter them into more stable materials. Among natural polymer composite for long fiber is two-dimensional (2D) woven preform, comprising two yarns, a warp yarn in the vertical direction and weft yarn in the horizontal direction that are interwoven together. The advantages of 2D woven preform are good dimensional stability in warp and weft direction, high yarn packing density, high out-of-place strength, low shear rigidity and good formability (Song *et al.*, 2012). To obtain the best-woven preform for the reinforcement in composite, consideration must be given to the strength, stiffness, and lightweight material.

Recycling and Renewability Issues of Kenaf Reinforced Composites in the Automotive Industry

Waste management is an emerging issue all over the world. This is because of the large amount of waste that is being generated daily and the impact of such waste is hazardous to the environment and living beings. With the rapidly increasing volume of vehicles, there is a parallel need to increase waste management initiatives by governments across the world and also on modern facilities for reuse and recycling of waste materials. The automobile is a major material consumer. Increasing production of vehicles is the key driver for the growth of the automobile market. The production of automobiles results in the generation of waste materials, which are recycled by many manufacturers as it helps to resolve supply shortage during the manufacturing process. The average vehicle is a mix of materials: Steel body frame, glass windows, rubber, lead batteries, and copper wires (House *et al.*, 2011). Steel is one of the most important materials in automobiles because of its toughness, durability, and malleability, but it remains very heavy, and for this reason, manufacturers have been trimming down its use. Composite materials are extending the horizons of designers in all branches of engineering. Eco-friendly biocomposites from plant-derived fiber are one of the novel materials in this era, not only as a solution to the growing environmental threat but also as a solution to the uncertainty of the petroleum supply (Mohanty *et al.*, 2000). Kenaf fiber (renewable material) reinforced nonbiodegradable polymer-based composites are gaining market demand in light of increasingly strict environmental regulations, and have thus attracted much industrial attention. Kenaf reinforced composites manage to overcome the challenge in replacing conventional glass-reinforced plastics with parts that exhibit structural and functional stability during storage and use, yet are susceptible to microbial and environmental degradation upon disposal, with no adverse environmental impact (Mohanty *et al.*, 2002). Since kenaf reinforced composites are derived from renewable resources, material costs can be markedly reduced with their large-scale usage. Their unique balance of properties would open up new market development opportunities for various biocomposites in the 21st century "green materials" world.

Future Prospects of Kenaf Fiber in the Automotive Industry

Kenaf fiber provides a lot of benefits to both the automotive industry and environment, such as minimized dependency towards nonrenewable energy/material sources, lower pollutant emissions, lower greenhouse gas emissions (Begum and Islam, 2013), increased energy recovery, end of life biodegradability of components (Akil *et al.*, 2011), reduced fuel consumption, and reduced weight of vehicles. Even though the advantages of kenaf fiber give specific benefits to the environment, all these properties should be supported by a quantitative analysis. In this aspect, Joshia *et al.* stated three comparative life cycle assessment studies to assess the overall environmental performance. This research led to specific applications, and analysis in the study showed that natural fiber composites are environmentally suited to replace the conventional fiber composites on most midpoint indicators. Drivers of superior environmental performance are expressed from the comparative analyses below (Begum and Islam, 2013):

- Less environmental impact from natural fiber production as compared with glass fiber production.
- Substitution of the matrix (synthetic polymer) by a higher content of natural fiber in the composite.
- Improvement of fuel efficiency and less used phase emissions due to weight reduction.
- Energy and carbon credits from the end of life incineration of natural fibers.

Reinforced plastics based on natural, primarily plant-derived substances show the promise of providing this and may become one of the material revolutions of this century. The automotive industry is one of the industries that need the "green" composites the most so as to produce vehicles with less weight and fuel efficiency. Faced with the pressure to produce fuel efficient and low polluting vehicles, the industry has utilized fiber reinforced plastic composites to make lighter products. However, fabricating the composites is energy intensive and polluting, while the durability of conventional composites is often seen as an advantage. Glass, carbon, and aramid fiber reinforced polyester, epoxy, and other similar resins are difficult to recycle and hard to dispose of, and so will remain on Earth for hundreds to thousands of years.

Conclusion

Based on the evaluation, biocomposites manufactured from kenaf fibers have received continual acceptance by industries around the world, even though it has not been rapid. Kenaf biocomposites have a promising potential to substitute petrol-based composites like glass-fiber composite as they have comparable mechanical and physical properties to the latter. In some countries, biocomposite technology is relatively new; however, it has a bright future to grow through constant research and development as well as ingenious commercialization strategy. Approaching manufacturers and helping them to implement good biocomposites production process to attain high-quality biocomposites is crucial. To ensure a continuous supply of high-quality kenaf fibers to meet the rising demand of kenaf biocomposites, the upstream is also required to practice better kenaf plantation procedures. Both upstream and downstream need to work together meticulously to ensure persistent development and acceptance of kenaf fiber-based biocomposites in various applications.

Lignin: A Renewable Raw Material

Francisco G Calvo-Flores, Modeling and Molecular Design Group, Organic Chemistry Department, Faculty of Sciences, University of Granada, Spain

© 2020 Elsevier Inc. All rights reserved.

Introduction

The name *lignin* is derived from the Latin term *lignum*, which means wood (Calvo-Flores *et al.*, 2015). It was introduced by the Swiss botanist A. P. Candolle (1778–1884) in 1819 (Jouanin and Lapierre, 2012). Under the name *lignin* we can find a group of plant-derived polymers with diverse structures (Huang *et al.*, 2019).

Lignin plays a multifunctional role in plants: It has a structural function giving rigidity and hardness to plant tissues. In addition, lignin plays an important biological function, because it forms an effective defensive barrier against insects and fungi attacks, allowing the efficient transport of water in the vascular tissues and it prevents the absorption of water by other plant components as polysaccharides in plant cell walls (Huang *et al.*, 2019; Liu *et al.*, 2018).

Lignin is the second most abundant organic substance in plants, and constitutes 30% of the nonfossil organic carbon in nature, and it is the natural raw material with the highest content of aromatic moieties (Huang *et al.*, 2019).

Chemically, lignin is a randomly cross-linked, aquiral polymer, formed mainly by three units with a phenolic core, known as monolignols. Monolignols are joined to some carbohydrate moieties to form an amorphous structure (Calvo-Flores and Dobado, 2010).

The three basic monolignol constituents of lignin are p-Coumaryl alcohol, Coniferyl alcohol, and Sinapyl alcohol abbreviated as M1_H, M1_G, and M1_S, respectively (Fig. 1). The three basic monolignols have a common origin: The phenylalanine molecule. The three major phenolic structures are present in the polymer and they form p-Hydroxyphenyl (H), Guaiacyl (G), and Sinapyl (S) residues. In addition, other less abundant monolignols have been detected in the polymer (Li and Chapple, 2010).

Free monolignols in plants are not abundant, but rather exist as glycosylated derivatives of the former monolignols, which can be transported in the plant and stored in lignifying tissues. Glycosylated derivatives of monolignols are synthesized in plants by an enzymatic process between glucose-uridine diphosphate molecule and the corresponding monolignol (Calvo-Flores and Dobado, 2010; Wang *et al.*, 2013b). The polymerization process in plants is known as lignification (Wang *et al.*, 2013b).

It is very important to point out that there is not a unique lignin in nature. There are remarkable structural differences depending on the plant species (Liu *et al.*, 2018).

In addition, in the paper industry, as a result of pulping process, a family of by-products called lignin are obtained every year (Gratzl and Chen, 1999; Zhong and Nie, 2018).

Fig. 1 Monolignols and aromatic residues in lignin.

Table 1 Proportions of monolignols in wood and herbaceous plants

Type	<i>p</i> -Coumarin alcohol	Coniferyl alcohol	Sinapyl alcohol
Softwood	<5%	>95%	0%
Hardwood	0%–8%	25%–50%	45%–75%
Herbaceous plants	5%–55%	35%–80%	20%–25%

Because of the structural diversity of lignin, it would be more precise to talk about lignins as a family of randomized polymers formed in plants and as a by-product of the paper industry with different functional groups depending on the pulping processes and the reactions that take place in such procedures.

Natural occur lignins (native lignins) can be classified according to two criteria: Plant taxonomy and the rate of basic phenolic units (Barros *et al.*, 2015; Espiñeira *et al.*, 2010). Considering the first criteria, lignins can be divided in three categories (Zhou *et al.*, 2016):

- (1) Angiosperm lignins (hardwood plants)
- (2) Gymnosperm lignins (softwood plants)
- (3) Grass lignins (herbaceous plants)

This classification has shown many exceptions; for this reason a more robust criteria has been developed on the basis of the abundance of the basic phenolic moieties in the polymer (Espiñeira *et al.*, 2010; Hatfield and Vermerris, 2001):

- (1) Type-G
- (2) Type-G-S
- (3) Type-H-G-S
- (4) Type-H-G

In case of softwood and hardwood, lignin is preferentially type-G and type-G-S respectively. For herbaceous plants lignin is basically type-H-G-S. However, proportions of monolignols are variable in every group, and very dependent on the species (Patil *et al.*, 2016) (Table 1).

The diversity of lignins arise from two facts: The different types and proportions of monolignols in the polymer and the different ways that monolignol linkages are produced, which lead to several C–C and C–O.

Monolignols play the role of building blocks but they are joined with several types of linkages. In consequence, different C–O and C–C bonds may be formed between monomers.

Fig. 2 shows some C–O and C–C bonds between monomers.

- (1) Monolignols represented on the right are noted with primes (')
- (2) The carbon atoms linked to another carbon chain are named with number 1
- (3) Carbons of side chains are named with α , β , and γ , starting with the closest atom to the aromatic ring

According to this nomenclature only eight types of bond arrangement show significance:

- (1) β - β' , β -1' and 5-5' for carbon–carbon bonds
- (2) β -O-4, α -O-4', and 4-O-5' for carbon–oxygen bonds
- (3) β -5'/ α -O-4', β - β' / α -O- γ' for carbon–carbon and carbon–oxygen bonds

Several phenylpropane type linkages have been described for carbon–oxygen and carbon–carbon bonds.

According to this data, some structural models for native lignin have been developed for softwood lignin (Neish, 1968; Glasser *et al.*, 1976; Adler, 1977) and for hardwood lignin (Nimz, 1974). In all cases such models must be considered as approximate because of the diversity of methods for taking information and structural data of the fragments.

Physical and Chemical Properties of Lignins

As any other biopolymer, lignin has been studied through the years to determine their properties and their structure. The main reports about their physical and chemical properties are related to:

- (1) Molecular weight
- (2) Dispersity index
- (3) Solubility
- (4) Thermal properties

Molecular Weight

Molecular weight (Lapierre, 1999; Vanholme *et al.*, 2010; Dong and Liu, 2012) is one of the more common parameters used for the characterization of lignin. This is a key property for the description of native lignins, but even in the present, still remains under

Fig. 2 Bonds formed between monomers. (top) C—C bonds, (bottom) C—O bonds.

debate because of the diversity of lignins in herbaceous plants and trees and the difficulty of sample preparation. Despite all these difficulties researchers agree in a M_w of isolated lignin in a 10^3 – 10^5 range depending on the plant species and the isolation and measuring methods. For softwood, values of M_w is greater than $2 \cdot 10^4$ and lower values for hardwood.

Dispersity Index

The dispersity index is a parameter used for the description of polymers to measure the molecular weight distribution expressed as $D_m = M_w/M_n$, when M_w is the weight-average molar mass, or molecular weight, and M_n is the number-average molar mass (Jones, 2010). Experimental data agree with the idea that soluble lignins and their derivatives show a remarkable dispersity with values that may vary from 2.5–3.0 to over 10–11, depending on the lignin origin (Brauns, 1962).

Solubility

From the first studies of lignin, solubility has been shown to be a key aspect for lignin handling (Maurer and Fengel, 1992). Native lignins obtained directly from biomass are insoluble in water and in most common organic solvents. To solubilize lignin, modifications must be performed to provide such goal. Generally it is necessary to carry out a pretreatment of lignin. In 1956 Björkman developed a technique for spruce wood that dissolves more than 50% of the lignin residue with a mixture of water-dioxane, if milled thoroughly (Björkman, 1954). Other pretreatments are based on thermal procedures, with proper solvents mixtures. Most of these procedures assume a partial degradation of native lignin into lower molecular weight fragments.

Thermal Properties

As any other polymer, lignin can be characterized by some parameters as T_g (glass transition temperature). Glass transition temperature is a parameter used for amorphous or semicrystalline polymers when they transform from a glassy state to a viscous and rubbery state. For this data, a range of values is obtained. T_g values for lignins (Irvine, 1985) from about 200°C to 500°C have been found (Laborie *et al.*, 2004).

About the Structure of Lignin

Despite the fact that lignin has been studied for decades, the understanding of such polymer has not been a simple task. The first attempts to unravel its structure were done in 1875 by Bente (1875). Those preliminary experiments showed for lignin a nature constituted by aromatic units. Other important step was when in the last decade of the 19th century Benedikt and Bamberger (1891) demonstrated that methoxy groups were an essential component of lignin. Along the years, many scientists have developed studies for the characterization of lignins, including spectroscopic methods, which have contributed to the development of “logic” models of lignin structure.

The first idea that can be extracted from such studies is the great structural diversity of lignins. Lignin is a key component of plants, and because of the vegetal kingdom’s biodiversity, lignin shows structural differences depending on the origin. There is not a unique technology capable to isolate lignin from nature or from other sources such as the paper industry. This is a real task for the valorization of lignin as a renewable raw material.

Basic Data for Determination of Lignin Structure

(1) Elemental analysis and empirical formulae

As with any other organic molecule, the elemental analysis of lignin has been carried out (Brauns and Brauns, 1960). Many researchers the last century determined the elemental composition of a variety of lignins. Some conclusions can be obtained (Huang *et al.*, 2019):

- (a) In native lignins only carbon, hydrogen, and oxygen can be found.
- (b) Average of these three elements varies depending on the source and the isolation method. Composition of lignins can be described in terms of structural units of nine atom carbons (C9).

According to experimental data, in case of milled wood lignin (MWL) for typical softwood and hardwood, the formulae are $C_9H_{8.3}O_{2.7}(OCH_3)_{0.97}$ and $C_9H_{8.7}O_{2.9}(OCH_3)_{1.58}$, respectively (Forss, 1966). It is important to remark that in such expressions, methoxy groups are highlighted because they contribute for differentiating monomer units in soft and hard woods (Sjostrom, 2013).

(2) Molecular weight determination

Molecular weight is a basic value that has been used in chemistry for characterization of any molecule, and lignin is not an exception. Despite the long time since the first studies were made, the molecular weight for lignin is still under debate, and values are not universally accepted for the same reasons that have been discussed before: The diversity of the starting material and the different methods for sampling isolation and analysis.

Four parameters are used as an approach for the concept:

- (a) Mole fraction
- (b) Weight fraction
- (c) M_n (number-average molar mass)
- (d) M_w (mass average molar mass)

In all cases, a key problem, as in any other property in lignin, is related to solubility of samples of lignins in organic solvents because almost always, an insoluble fraction remains in sample preparation, which disturbs the final results.

Common techniques used for such determinations are gel-permeation chromatography, light scattering, vapor-pressure osmometry, or ultrafiltration.

(3) Determination of functional groups in lignin

Despite the structural complexity of lignin, the analysis of native lignins has shown a relatively limited number of functional groups:

- (a) Methoxy groups (Freudenberg *et al.*, 1929)
- (b) Hydroxyl groups (phenolic and aliphatic) (Tiainen *et al.*, 1999)
- (c) Carbonyl groups (Li *et al.*, 2015)
- (d) Carboxyl groups (Lin and Dence, 2012)

The first results were obtained based on classical analytical methods:

- (1) The earlier studies of native lignin showed the presence of methoxy groups attached to aromatic moieties. The reactions used for such purpose were based on reactivity of lignin refluxing with HI to give methyl iodide, which was detected when it was treated with a solution of silver nitrate to give a solid silver iodine (Patil *et al.*, 1967). The same process may be positive when ethoxy groups are present. The percentage of methoxy groups depends on the origin of lignin and the method used for lignin isolation.
- (2) Hydroxyl groups attached to aromatic rings has been detected, for example, by acetylation of lignin followed of aminolysis. In case of aliphatic hydroxyl groups the average is calculated comparing total -OH groups detected with phenolic hydroxyl groups (Patil *et al.*, 1967; Serrano *et al.*, 2018).
- (3) The presence of carboxyl groups was detected by reaction of lignin with phloroglucinol and concentrated hydrochloric and UV spectroscopy (Speer, 1987).
- (4) Carbonyl groups in lignin have been determined chemically by calcium acetate method based on ion-exchange resin (Lin and Dence, 2012).

Characterization of Lignin by Spectroscopic Methods

Spectroscopic methods are the most reliable techniques for determining the structures of chemical substances and have carried out in the last decades an unstoppable development even for the more complex molecules as polysaccharides and proteins. Lignin has also been studied intensively by spectroscopic methods (Stark *et al.*, 2016), which has clarified many aspects of its structure, giving rise to much more precise models than those obtained exclusively by chemical methods (Sjostrom, 2013; Stark *et al.*, 2016).

Fourier-transform infrared spectroscopy (FTIR) spectroscopy, Raman spectroscopy, ultraviolet, and especially nuclear magnetic resonance of protons and carbon have been the main techniques used for structural elucidation on lignins.

FTIR spectroscopy may be used on native lignin in solid state (Faix, 1986). Very small quantities are required. Specific absorptions of the functional groups may be detected. They agree with previous results obtained with chemical tests, but information on connectivity of the fragments and moieties remains confused with this spectroscopy technique. Something parallel occurs with Raman spectroscopy or UV spectroscopy. The presence of functional groups and atom groupings can be detected, but a more approximative idea of the real structure of lignin is not possible.

The study of nuclear magnetic resonance (Chen and Robert, 1988) of protons and carbon of native lignin and fragments has contributed to give a more precise idea of lignin structure despite the fact that most chemical shifts for protons are observed in a rather limited range and the low abundance of ^{13}C nucleus that suppose long acquisition times for sample analysis.

Even with such limitations, very useful information about lignin structure may be obtained as a real ratio of monolignols in polymer and their connectivity.

Models of Lignin

Hardwood models

There is not a unique model that can properly describe hardwood lignin. Many studies have shown significant variations in lignin, such as syringylpropane/guaiacylpropane ratio (*S/G* ratio), arylglycerol- β -aryl ether (β -O-4), degree of condensation, and elemental and methoxyl contents, depending on the hardwood species (Santos *et al.*, 2012; Hori and Meshitsuka, 1999; Shimizu *et al.*, 2012). These structural variations among species appear to be correlated to the factor syringyl/guaiacyl ratio. A new method to predict the *S/G* ratio of total lignin in wood was developed, using a calibration line established by the syringaldehyde/vanillin (*S/V*) ratio (nitrobenzene oxidation) and the *S/G* ratio (^{13}C NMR) of MWL.

Fig. 3 shows a schematic representation of lignin for hardwood species according to literature data. Some characteristic functional groups are highlighted.

Softwood models

Structural models for softwood lignin have been proposed mainly based on degradation products of native lignin (Sakakibara, 1980). As for hardwood lignin models, there is not a single model. Structural analysis of degradation products of softwood lignins obtained for several methods (for example by hydrolysis with dioxane/water and catalytic hydrogenolysis) may be performed. More than 20 different fragments obtained by this way, have shown a good concordance with the various analytical data obtained so far in the lignin chemistry. A model of softwood lignin is given in Fig. 4.

Fig. 3 Lignin for hardwood species.

Herbaceous plants models

Straw lignins of herbaceous crops (Dalimova and Abduazimov, 1994; Karmanov *et al.*, 2014) are structurally different from those of softwood or hardwoods lignins (Buranov and Mazza, 2008). They possess characteristic alkali solubility because of the availability of alkali-labile ester bonds between hydroxycinnamic acids and hemicelluloses (arabinoxylans) in lignin/phenolics-carbohydrate complexes (see Fig. 5). In addition their monomeric composition contains all three H, G, and S subunits with the H subunit up to 15% in rice straw, whereas hard and soft wood lignins contain mainly G and S subunits (except for compression wood which contains H and G units). In this regard, the lignin in flax sheaves is more similar to hardwood lignin as it contains G (75%) and S (25%) subunits.

Commercial Lignins

The so-called commercial lignins are those obtained in the paper industry, and those that can be isolated from plants. Most of them are obtained from the paper industry (Calvo-Flores and Dobado, 2010).

In the paper industry, the goal is to obtain cellulose as pure as possible for paper manufacture by the pulping process. In this procedure lignin and hemicellulose are dissolved from the lignocellulosic biomass to isolate cellulose, and the remaining lignin as a by-product must be separated. Every year a huge amount of such lignins are produced around the world (Constant *et al.*, 2016). A characteristic of such lignins is that they are chemically modified if compared with native lignin, depending on the chemicals used for pulping.

Five main groups can be described.

- (1) Kraft lignin
- (2) Sulfite lignin
- (3) Soda lignin
- (4) Organosolv lignin
- (5) Steam-exploded lignin

- (1) Kraft lignin

One of the more popular pulping processes is kraft pulping, covering greater than 80% of the pulping capacity of the paper industry (Hu *et al.*, 2018). It was developed in Germany in 1879. This method cleaves the β -O-4 linkages between the C9 units in lignin using sulfides in an alkaline environment with temperatures up to 170°C (Chakar and Ragauskas, 2004). With such pulping method, the native polymer is fragmented into lower molecular mass units. A hypothetical model of kraft lignin is given in Fig. 6 but the structure of kraft lignin is still under revision, and some relatively recent papers can be found in literature (Crestini *et al.*, 2017; Mattsson *et al.*, 2017).

Kraft lignin is produced at a rate of 40 million tons per year (Crestini *et al.*, 2017).

Fig. 4 Lignin for softwood species.

(2) Sulfite lignin

The acid sulfite pulping process was first developed in Germany in 1840. Lignin is dissolved by treatment with SO_3^{2-} salts or HSO_3^- in case of acidic environment, at a range of temperatures from 50°C to 160°C (Ahlm and Brauns, 1939; Gellerstedt *et al.*, 1975).

Ether bonds are broken and modified lignin is formed with $-\text{SO}_3\text{H}$ groups linked to lignin (Ahlm and Brauns, 1939). The higher number of such groups produce a higher water solubility and lignin can be separated from cellulose by washing out, but with a higher molecular weight fragments than kraft lignin (Table 2).

The sulfite lignin residue, once water is removed, has the commercial name of lignosulfonate, with an estimated production in a rate 8–10 million tons per year (Crestini *et al.*, 2017; Li and Ouyang, 2012). Structure of sulfite lignin is given in Fig. 7.

Soda pulping process used to be used for pulping of nonwood materials, such as straw, sugarcane bagasse, flax, etc., that are digested with aqueous solutions of sodium hydroxide at temperatures of 160°C or lower (Chakar and Ragauskas, 2004). The

Fig. 5 Alkali-labile ester bonds between hydroxycinnamic acids and hemicelluloses (arabinoxylans) in lignin/phenolics-carbohydrate complexes.

Fig. 6 Hypothetical model of kraft lignin.

Table 2 Sulfite processes

Process	Chemicals	pH range	Temperature range (°C)
Bisulfite	HSO_3^-	3–5	150–175
Neutral sulfite	$\text{HSO}_3^-/\text{SO}_3^{2-}$	6–57	150–175
Acid sulfite	$\text{SO}_2/\text{HSO}_3^-$	1–2	125–145
Alkaline sulfite/anthraquinone	Na_2SO_3	9–13	50–175

**Fig. 7** Structure of sulphite lignin.

procedure is known from 1853. There are some similarities between soda pulping and the kraft process as cleavage of lignin-carbohydrate linkages and depolymerization of the lignin and its recondensation take place. Lignin depolymerization occurs principally by the cleavage of aryl ether bonds, first in phenolic units and in a later phase of delignification in nonphenolic units. The generation of free phenolic groups in such reactions results in lignin fragments that are soluble in the alkaline environment, but insoluble in pure water. Soda lignins are significantly different from liginosulfonates, which shows lower molecular weight. Soda lignin is sulfur free and is obtained with low levels of sugar and ash contaminants.

(3) Organosolv lignins

Organosolv lignins are a group of lignins obtained by direct extraction from biomass of the polymer with organic solvents (Lindner and Wegener, 1988). Most organic solvents are used together with water and some chemicals are added to improve the yield of the process at high temperature and/or pressure (Table 2). Once the solvent treatment is performed lignin is isolated by precipitation in acidic media. All lignins isolated by such procedure are sulfur free and show a structure more similar to native lignin.

Several procedures have been described in literature. Alcohols are the most widely used solvents. Lignins extracted by such methods, use to be nominated according to the experimental process. Table 3 summarizes some of the most popular procedures that have been described. However, only Alcell and Organocell lignins are commercially available.

(4) Steam-exploded lignin

This type of lignin is obtained when wood is treated with steam at high temperature/pressure (Nonaka *et al.*, 2013; Grāvis *et al.*, 2010), and then a sudden decompression is applied in the presence of some chemicals. In these conditions a partial hydrolysis of lignin occurs, and a water-insoluble lignin is obtained with a low level of impurities. The polymer shows a slight

Table 3 Organosolv lignins and procedures

<i>Organosolv lignin type</i>	<i>Solvent/catalyst system</i>
Alcell	Ethanol/water
Organocell (Lindner and Wegener, 1988)	Pulping with methanol, followed of NaOH and anthraquinone in methanol
Acetosolv	Acetic acid/Chlorhydric acid
Acetocell	Acetic acid/water
Formacell (Lindner and Wegener, 1988)	Acetic acid/ Formic acid/Water

reduced molecular mass because partial acid hydrolysis reactions take place under these conditions. This procedure is often combined with enzymatic hydrolysis to obtain carbohydrates for fermentation reactions.

Applications of Lignins

As mentioned above, lignin is the second most abundant biopolymer in nature, and the natural substance with a greater presence of aromatic moieties. In fact it is the largest source of aromatic substances without considering the oil.

Many researchers and industrialists have coined the sentence “with lignin you can do anything but money” (Graichen *et al.*, 2017). This sentence supposes a quite realistic approach to the current picture on lignin. The chemical industry is mainly based on oil as source of raw material. Despite the horizon of a world without oil, it has been delayed for a few years due to more efficient oil extraction methods, so the obtention of raw materials from renewable sources is a necessary goal to develop a more sustainable economy, with a better CO₂ balance and ready for a future based only in renewable sources (Graichen *et al.*, 2017; Langeveld *et al.*, 2012).

Lignin as a renewable raw material from biomass with two sources:

- (1) By-product of paper industry
- (2) Direct extraction from plants

The main source of lignin is the paper industry, which produces huge amounts of chemically modified lignin as a by-product. As it has been described before, depending on the method to separate cellulose from biomass in pulping, several types of commercial lignins are obtained.

In the last decades there has been progress on the valorization of lignin, but considering the enormous quantities of lignin that the paper industry produces every year, and the potentiality of this raw material as a source of fine chemicals, especially aromatic compounds, the results are still modest for obtaining commercially valuable products. Two main directions can be considered for lignin valorization:

- (1) The use of lignin keeping the polymeric structure with chemical modifications of the material or not
- (2) Valorization of lignin by depolymerization reactions to give simple aromatic molecules

Applications of Unmodified Lignins

Combustion

Lignins obtained from the paper industry are the more available group of these polymers.

The major application of lignins in the paper industry is as fuel in the same factory to obtain energy. Black liquor is the spent liquor formed in the kraft process. Pulpwood is transformed into paper pulp by removing mainly lignin, hemicellulose, and other extractable materials, which are separated from cellulose fibers. When it is used in the sulfite process the spent liquor is usually called brown liquor, but other terms such as red liquor, thick liquor, or sulfite liquor are also used for this pulping technology. It is assumed that approximately seven mass units of black liquor are produced in the manufacture of one mass unit of pulp (Biermann, 1993). Water is removed from black liquor and the solid is burned. Another more efficient option than the conventional recovery boiler for power production (Speight, 2014) is to carry out gasification, which has the potential to achieve higher overall energy efficiency (Yu *et al.*, 2018).

In this field, lignin is used as additive for biomass heating as binder of pellets, artificial fire logs, and other wood derivatives. The introduction of lignin in these materials are very convenient because it is able to improve fuel properties.

Direct applications

Lignin is a nontoxic polymer and a quite inert substance when interacting with living organisms. This behavior and some properties such as natural antioxidant (Yu *et al.*, 2018; Mahmood *et al.*, 2018), free radical scavenger (Pan *et al.*, 2006), or its capacity to link to cations, have meant that lignin may be used in the preparation of commercial products for agriculture (García *et al.*, 1996), livestock (Baurhoo *et al.*, 2008), or in medicine to protect against the development of different diseases (Vinardell and Mitjans, 2017).

For example, kraft lignin or steam-exploded lignin has shown antioxidant activity in human red blood cells, and water-solubilized lignin derivatives present antiviral activity in vitro, and some other lignin derivatives have shown antibiotic properties, and even anticarcinogenic activity. Based on these properties, some applications are under development (Larrañeta *et al.*, 2018).

Some sulfur-free lignins such as commercial Alcell lignins, have exhibited prebiotic effects in monogastric animals (Baurhoo *et al.*, 2008). The addition of this kind of lignins to animal feed may improve the growth of beneficial bacteria and morphological structures in the intestines.

On the other hand, lignin fragments have shown bactericidal properties so that they may help control intestinal pathogens in livestock products and lignin-based biopolymers have antioxidant capacity (Mahmood *et al.*, 2018). However, much research is still required to determine optimum lignin dosages for livestock and the potential effects on the environment.

Related to human health and illness (Vinardell and Mitjans, 2017), some tests to reduce the genotoxicity in drugs and side effects on patients have been carried out and in case of lignin dietary fiber (Lábaj *et al.*, 2003), it has shown to be important in absorbing bile acid and thereby influences lipid metabolism (Eastwood and Girdwood, 1968).

Technical Applications

Lignin sulfonates are probably the most abundant lignin derivative. They have shown some interesting applications as low cost binders in coal briquettes (Saranchuk *et al.*, 1995), ceramics (Somiya *et al.*, 2003), mineral dusts or wood derivatives as boards or plywood (Pizzi, 1989). Because they are not hazardous, they have been used as eco friendly binders for furniture and other wood products (Grāvītis *et al.*, 2010), but probably the more extended use is as moisture-retention agents and dust suppressors in public works, unpaved roads, airports, sports facilities, or racing circuits. Added to soil, dust particles remain in the ground without entering the atmosphere (Gargulak and Lebo, 1999).

Lignin sulfonates are used as additives in concrete mixtures (Mullick, 1996) because they prevent lumping and settling of unsolved particles in suspension. Other applications of lignin sulfonates can be found in leather tanning factories (Suparno *et al.*, 2004), ceramics (Cerrutti *et al.*, 2012), and gypsum-board manufacture (Northey, 2002). On the other hand, lignin sulfonates are able to stabilize emulsions (Gharehkhani *et al.*, 2018) of immiscible liquids making them highly resistant to breakdown, for example asphalt emulsions (Gharehkhani *et al.*, 2018; McIntosh, 1952), pesticide formulations (Wilkins, 1983), wax emulsions, pigments, and dyes (Wilkins, 1983; Rojas *et al.*, 2007).

Lignin sulfonates present a remarkable affinity for some metal ions because of their polar groups with chelating properties (Ge and Li, 2018). Used low concentrations (ppm-scale) may prevent scaling in hot and cooling waters or remove toxic metals from waters (Crist *et al.*, 2005). Several commercial derivatives are used as micronutrient transporters or as cleaning and decontaminating agents in water and soils (Wise, 2000).

Lignin as a Copolymer Component

The incorporation of lignin in the diverse formulations of synthetic polymers has been investigated for decades to modify the properties of some polymers and to improve environmental behavior of some formulations. Despite the efforts, practical results in this field are still limited and modest.

Two approaches have been developed in this field. First is to use lignin without chemical modification within the polymer. The second approach involves the chemical transformation of lignin to improve the reactivity, before the incorporation into the polymer.

Formulations without chemical modification of lignin

Because of its phenolic nature, it is not difficult to use lignin in polymer chemistry; for example in phenol-formaldehyde resins (Siddiqui *et al.*, 2017). Such resins are widely used in technical and industrial applications (Siddiqui *et al.*, 2017; Pye, 2008) as adhesives for plywood (Wang *et al.*, 2018), chipboard, medium-density fiberboard, and oriented strand board (Inamuddin, 2016), in the manufacturing of mineral wool, abrasives, refractory and friction materials, and rubber products. The classical method for the synthesis of such resins consists to polymerize mixtures of phenol and formaldehyde in acidic or basic media. Depending on proportions and the conditions the so-called resol (Tkachuk *et al.*, 1971) and novolac (Chaplan, 2014) polymers are obtained for acid or basic reactions, respectively.

Acetosolv, organosolv, or hydrolyzed lignins have been used instead of pure phenol (Tachon *et al.*, 2016) in phenolic resins to produce modified polymers. Such materials exhibit satisfactory properties with good curing characteristics. In binders, about 50% of Kraft lignin or lignosulfonate lignin can be added instead of phenol to phenol-formaldehyde resins without substantially modifying the final product properties. The substitution of phenols by lignins (Tachon *et al.*, 2016) is not only environmentally friendly but also less expensive than other binders used in the wood-composite industry (El Mansouri *et al.*, 2018). Some physical and mechanical properties are modified, for example, in novolac-type resins, the addition of lignin leads to polymeric systems with increased rigidity. Lignin has been used in formulations of polyolefins polymers, polyesters, acrylamide, or polyurethanes, in some cases as an additive, and as macromonomer in others.

For example, the addition of 30% of dry lignin powder to high-density polyethylene (Sameni *et al.*, 2018), low-density polyethylene (Lüftl and Visakh, 2016), or polypropylene (PP) (Morandim-Giannetti *et al.*, 2012) can modify the mechanical and

technical properties of polymeric materials. Lignin has been shown to be a stabilizer against the photo-oxidative degradation of common polymers such as polyolefins (Mikulášová *et al.*, 2001). However, polymers as PP or polyethylene are materials that are highly resistant to biodegradation. This is a serious environmental problem, because of the massive use of such polymers together with the great deficiencies about recycling these polymers.

Lignin-based thermoplastic copolyesters can be synthesized by using Kraft lignin (Guo *et al.*, 1992; Guo and Gandini, 1991) as a macromonomer to form a high-molecular-weight polymer. Kraft lignin is polymerized with sebacoyl chloride (decanedioyl dichloride) in the presence of triethylamine in N,N-dimethylacetamide (DMAc) (Hori and Meshitsuka, 1999; Binh *et al.*, 2009). The resulting polymer is an eco friendly material that exhibits good thermal stability up to 200°C.

Precured polyurethanes can be synthesized by the reaction of Kraft lignins (Yoshida *et al.*, 1987), or organosolv lignins (Yoshida *et al.*, 1987; Hatakeyama, 2002) polyols such polyethylene glycol or polypropylene glycol and methylene diphenyl isocyanate and a plasticizer. Rigid polyurethane sheets and foams can be prepared by this procedure.

German researchers Pfister and Nägele have obtained promising results, from the Fraunhofer Institute for Chemical Technology. They have developed a new thermoplastic material, named ARBOFORM (Nägele *et al.*, 2002). This new bioplastic material is made by mixing specific types of low-content sulfur lignins with natural fibers from several plants and natural additives such as wax. Sulfur-free lignins are usually water-soluble, so they are unsuitable for manufacturing certain objects such as toys or household items. With the aid of additives, the bioplastic can be modified in such a way that it survives contact with water and saliva undamaged. This material is a plastic granulate that can be melted and injection-molded, so it can be applied with conventional plastic-processing machines in just the same way as a petrochemical thermoplastic material (Nedelcu *et al.*, 2014). The final product resembles highly polished wood, or may have a more matte finish and look like the plastic used in most household items, and it is highly recyclable.

Polymeric formulations with chemical modification of lignin

The aromatic moieties of lignin, theoretically, may be subjected to a wide range of reactions as alkylation, dealkylation, oxyalkylation, amination, carboxylation, acylation, halogenation, nitration, hydrogenolysis, methylation, oxidation and reduction, sulfomethylation, sulfonation, silylation, phosphorylation, and nitroxide formation (Loh and Kai, 2018; Podschun *et al.*, 2015). Such modifications have mainly been used to improve dissolution of lignin into organic solvents and to determine the functional groups of lignin but they may be useful in the synthesis of copolymers with modified lignins.

One problem of lignin in polymer chemistry is that phenolic hydroxyl groups remains hindered into the lignin matrix, therefore, the reactivity of phenolic groups remains quite low if compared with phenol, to be incorporated in other polymeric materials properly. Some of these reactions provide a higher reactivity because the functional groups play a role of spacer.

Epoxy resins are well-known polymers with many applications. Most epoxy and phenoxy resins use epichlorohydrin as a major raw material to induce polymerization. Epichlorohydrin reacts with molecules such as bisphenol-A to yield polymers (van de Pas and Torr, 2017). Modified lignin can be added as a cross-linker material in phenol-formaldehyde resins, to give several resins (Nada *et al.*, 2003) and adhesives (Danielson and Simonson, 1998), but in most cases, lignin must be activated introducing more reaction sites towards formaldehyde. Lignin is modified by phenolization and/or demethylation. Phenolization increases the number of phenol units in lignin by reaction of lignin with phenol and demethylation increases the number of free OH groups in lignin by treatment with some chemicals, for example, molten pyridinium chloride. Both, additional phenol moieties and demethylation can be incorporated into the lignin structure by the reaction of lignosulfonate with phenol in sulfuric acid media. Two reactions take place in such conditions: Some new phenolic units are introduced into the lignin matrix and some lignin is hydrolyzed to give diphenolic moieties (Fig. 7).

On the other hand, an alternative strategy that has stirred growing interest is the use of pyrolytic lignin as a renewable resin from pyrolysis of biomass, due to the high yield of pyrolytic lignin and its easy assimilation into phenol formaldehyde formulations. Most of these pyrolytic lignins appear to be oligomeric alkylated phenolic units probably linked by CC bonds.

High-Value Products From Lignin

The higher task related to lignin is to use it as a true source for the preparation of high value materials, especially chemicals.

The first level for lignin valorization may be through thermal transformations. As most biomass or related substances, lignin can be transformed by gasification into syngas (Soomro *et al.*, 2018), mixtures of hydrogen and carbon monoxide. Syngas is per se a fuel used in combined cycle power plants and a valuable starting material for the synthesis of many chemicals. The coal and natural gas industries have used syngas for decades and this technology is well established, but lignin gasifiers based on lignin are still in an early stage of development.

However, the major challenge related to lignin is to obtain low molecular mass aromatic compounds as a real alternative to the petrochemical industry. The potentiality of this area is enormous, but the practical results are still modest. Every year a remarkable amount of work on this field is published (Hu *et al.*, 2018; Das *et al.*, 2018; Abad-Fernández *et al.*, 2019; Ragauskas and Yoo, 2019; Sun *et al.*, 2018).

To obtain high value molecules from lignin it is necessary to carry out an effective depolymerization of the polymer by thermochemical or chemical transformation processes.

Fig. 8 Oxidation reaction with a copper catalyst for lignin obtention.

The goal for such transformations is to obtain benzene toluene xylenes aromatics, as they are known in the petrochemical industry mixtures of benzene, toluene, and the o-, m- and p-xylene isomers, and other substances as cresols (o-, m- and p-isomers), catechol, resorcinol, benzoquinones, vanillin, or guaiacol. The state of the art remains at a very basic level, because the practical application of these techniques is still very modest.

Depolymerization of lignin may be produced by

- (1) Thermolysis: Pyrolysis of lignin by a rapid heating at elevated temperatures to give the so-called bio-oil, gas, and a solid residue (ash or char). Catalysts are often used in this procedure (Fan *et al.*, 2017).
- (2) Hydrogenolysis: Similar to the previous procedure but in presence of hydrogen as reducing agent (Cao *et al.*, 2018).
- (3) Hydrothermal hydrolysis: Lignin is converted into liquid mixtures when treated with water, which is used as hydrogen source, together with other chemicals (Ma *et al.*, 2014).
- (4) Depolymerization in acid media (Wang *et al.*, 2013a).
- (5) Depolymerization in base media (Pandey and Kim, 2011).
- (6) Oxidative depolymerization: Treatment with oxidants as chlorine, oxone, hydrogen peroxide, or peroxy acids (Wang *et al.*, 2013a; Lange *et al.*, 2013).

Vanillin

Vanillin is one of the more used food additives and flavoring agents in cosmetic and other household products (Taylor and Linforth, 2009). The natural sources of vanillin are insufficient for the industry requirements, and it may be synthesized from benzene, following several routes with conventional reactions on aromatics.

However, vanillin can be obtained from lignin. In fact, spontaneous decomposition of lignin produces vanillin. This is in part the cause of the typical odor of old books. The residual lignin of paper decomposes through the years giving the characteristic aroma of old books.

Vanillin has been produced by several companies from lignin (Fache *et al.*, 2015), but using lignin as raw material for vanillin synthesis is quite limited. Borregard is one of the world's leading suppliers of vanillin from lignin, based on the biorefinery concept. According to company reports, from 1000 kg of wood 3 kg of lignin may be obtained. The key step for lignin obtention is an oxidation reaction with a copper catalyst, which is recycled (Fig. 8).

Active Carbon and Carbon Fibers

Lignin is a good starting material for active carbon preparation. Activated carbons are used widely, as absorbents in removing a wide variety of both organic and inorganic substances, for example pollutants or impurities from liquid or gaseous phases because they form a very porous structure with a large internal surface area. Lignin may be used for that, because it is easily available and is inexpensive. The general method involves the pyrolysis of lignin under inert atmosphere to obtain a char that must be activated, by physical methods with the treatment of a gas as CO₂ or water vapor, or chemically by treatment, by impregnation with chemicals such as H₃PO₄, KOH, or NaOH (Hayashi *et al.*, 2000). Depending on the activating agent and other variables as activation time and temperature several surface areas and micropore volume can be obtained (Shendrik *et al.*, 2007; Suhas *et al.*, 2007). Such activated carbons have been tested, for example for treating gaseous streams (Song *et al.*, 2017) or as part of electric supercapacitors (Hayashi *et al.*, 2000; Hu and Hsieh, 2017).

Carbon fibers (CF) are materials composed of fibers with diameters from 50 to 10 μm, mainly conformed by carbon atoms that show low density, high flexibility and resistance, low weight, low thermal expansion coefficient, and are stable at

Fig. 9 Lignin transformation into selective chemicals.

high-temperatures values. These materials are focused on high technology sector, where the large-scale use of CF is driven by maximum performance and not by cost factors (Chung and Chung, 2012). Many researchers have considered lignin-based CF as an alternative (Yue *et al.*, 2017), comparing the process to current precursors (Yue *et al.*, 2017; Kadla *et al.*, 2002). Organosolv lignins and Kraft lignins have been tested as affordable precursors for the synthesis of CF. Lignin-based CF procedures are less energy intensive and emit around 22% less CO₂-equivalent greenhouse gas emission than conventional Polyacrylonitrile-based carbon fiber. Despite several challenges that must be overcome, lignin-based CF can be produced nowadays under limited mechanical properties, but enough to attend to some industrial branches. This has great potential for market insertion, emerging as a material with high technological impact, economically attractive, and environmentally sustainable (Souto *et al.*, 2018).

Nanoparticles From Lignin

Nanoparticles are materials having size ranges from 1 to 100 nm that have attracted the scientific community for their potentiality in diverse fields, such as catalysis, imaging, drugs delivery, energy-based research, or environmental applications. They can be classified many ways based on their properties, shapes, or sizes (Jeevanandam *et al.*, 2018). They can be synthesized both from organic or inorganic sources.

To valorize lignin, researchers have focused on using lignin as a renewable source to obtain nanoparticles (LNPs).

Some recent examples can be found in literature, indicating that recently LNPs have been obtained from several types of lignin using castor oil, ethylene glycol, or water as reaction media, and the resulting nanoparticles evaluated as anticorrosion agents (Rahman *et al.*, 2018). Kraft lignin is able to form stable and spherical nanoparticles enzymatically, in a nonmalodorous colloidal dispersion in water or organic solvent becoming an attractive bionanomaterial for many industrial applications (Mattinen *et al.*, 2018). But probably, one of the most promising fields related to LNPs applications is their use as carriers for drug delivery (Yiamsawas *et al.*, 2017). Lignin is a biocompatible and nontoxic material that can play an important rule in this area (Mattinen *et al.*, 2018; Figueiredo *et al.*, 2017; Dai *et al.*, 2017).

Conclusions

Lignin is the second most abundant organic substance in plants, and constitutes 30% of the nonfossil organic carbon in nature, and it is the natural raw material with the greatest content of aromatic moieties. The structure of native lignin is complex and diverse, depending on the plant species. But the major source of lignin is the paper industry, which through the pulping processes separates lignin from cellulose, and diverse lignin types are commercially available.

Despite the enormous amounts of lignin produced every year, the use of lignin as raw material for obtaining high value substances and consumer goods is still at a very basic stage in development. For the next few years, and with a world without oil on the horizon, the basic and applied research on lignin is a great challenge for researchers and industries. Probably the most important task for next few years will be the development of efficient and selective catalysts for lignin transformation into aromatic chemicals with reasonable yields for the petrochemical industry and a better use of lignin (Fig. 9).

applications. LVIs of homogenous basalt and glass fibre polymer composites are compared. Epoxy resin and the vacuum-assisted resin transfer moulding (VARTM) method were used to fabricate the composites. BFRP has superior LVI performance to CFRP due to its higher stiffness (Shishevan *et al.*, 2017).

Similarly, recycled carbon fibre composites were compared with treated recycled carbon fibre and virgin carbon fibre composites. Virgin carbon fibre composites showed an enhancement in damage protection, higher residual strength and angle of shear failure during impact. The damaged specimen was examined with an ultrasonic C scan, photography, and SEM. The fibre orientation is chosen to improve the property of the composites (Shi *et al.*, 2014).

The fibre orientation also influences the parameters in the polymer composites. Basalt fibre polyester composites were manufactured with three different fibre orientations. Among these, three 0° laminated composites showed better LVI results than the plain woven and cross ply laminates (Gideon *et al.*, 2014). Recently, researchers have focused on fibre metal laminates as an alternative, in order to enhance the LVI of the composite by adding metal layers into the polymer composites. Sharma *et al.* (2018) prepared Fibre Metal Laminate (FML) composites with glass fibre using the hand-layup technique followed by vacuum bagging. The specimens were fabricated with different layering thickness and it was concluded that the FML with 0.6 mm thickness and 90° orientations showed minor levels of cracking and deformation at the maximum force. For woven glass fibre reinforced composites manufactured with varying volume fractions using vacuum bagging techniques, the results showed that a volume fraction of 43%–44% gave a better impact resistance.

The damage resistance and post-impact of non-woven flax epoxy composites was studied by Habibia *et al.* (2018). With the help of c scan inspection, the damage mechanism was analysed. The damage was induced due to matrix cracking and delamination. An auxetic warp-knitted spacer fabric structure has outstanding mechanical properties, shear-resistance, cushioning property and energy absorbing abilities. Chang *et al.* (2017) used the same to study the impact resistance and energy

absorption capability under LVI. The negative value of Poisson's ratio means that it has a better energy absorption capability and impact resistance.

A cylindrically shaped object was also tested by [Khan et al. \(2016\)](#). They used filament wound glass fibre reinforced vinylester and epoxy-based pipe composites with a thickness of 6 mm and an internal diameter of 150 mm. A single bounce LVI tester was used with a spherical head steel impactor. During the elastic deformations, there was no gross damage, and at peak load there was damage initiation and propagation was observed. It was concluded that Glass Fibre Reinforced/Epoxy (GFRE) pipes required more energy to initiate damage than did Glass Fibre Reinforced/Vinylester (GFRV) pipes.

By varying the thickness of the composites, [Caminero et al. \(2017\)](#) investigated the damage resistance of CFRP epoxy composites to measure the influence on composite thickness and stacking sequences. C scan and micrographs were used to measure the failure mechanisms. It was observed that the damage resistance decreased with increasing impact energy and the thicker laminates absorbed less energy. Using a variety of fibres for the development of LVI for the studies, changing the matrix materials also influenced the LVI.

Flax fibre reinforced composites with different types of matrix, namely epoxy and Anhydride grafted Polypropylene (MAPP), have been used. From the results, it can be understood that the selection of two different matrixes highly influences the absorbed energy and the damage area, and the flax-MAPP composite was found to be 50% higher compared to the flax-epoxy composites. The orientation of the fibre has a limited contribution in the damage of the composites. The ductile nature of the thermoplastic matrix resulted in a decreased impact damage area, by between 38% and 59% ([Bensadoun et al., 2017](#)).

[Li et al. \(2017\)](#) investigated the LVI of GFRP composites with the energy ranging from 16.75 to 67 J. The damage analysis and failure mode of the composites were analysed for different levels. Numerical analysis was also carried out to confirm the experimental results in terms of load-time and central deflection-time curves.

Concerning the recyclability aspect, for the fully thermoplastic plastic composites, both the reinforcement and the matrix were made in polypropylene, as prepared by [Boria et al. \(2017\)](#). The polypropylene composites were subjected to LVI testing under different impact loading conditions. The composites showed a ductile performance and developed extended plasticity without a crack tip, and damage causes in the composites were due to yarn sliding, delamination and fibre fracture.

[Martins et al. \(2018\)](#) studied the tufting of woven carbon fibre composites and the impact on LVI and compression after impact. The density and the angle of tufting were varied to attain better results. The tufting of the fibre was performed in two different ways: transverse tufting and angular tufting. It was revealed that transverse tufting gives better results than angular and non-tufted composites, and an increase in the tufting density resulted in a decrease of the damaged area by 4 times and the ultimate compressive strength improved. Further extending the performance of the composites, [Ravandi et al. \(2017\)](#) investigated the effect of a stitched and unstitched woven flax/epoxy composite and LVI, with perforated and non-perforated damage. Flax yarn stitched composites reduced the intra-laminar fracture toughness of the flax fibre composite by 16%, but for the cotton yarn stitched composites the value was 5%.

[Mingmin et al. \(2016\)](#) investigated the LVI of 3 different alumina/epoxy/metal laminated composites with epoxy resin, with Al foil, Cu foil, and steel mesh as the metal interlayer. Different energy levels were used for the different composites, such as 5 J and 5.5 J for the A/A composites, 10, 15, and 19 J for the A/Al Composites, 19, 22, and 25 J for the A/Cu composites and 19, 25, and 30 J for the A/S composites. A/A has poor impact resistance and was penetrated at the lowest energy levels. An A/S composite has the best impact resistance, followed by the A/Cu and A/Al composites.

[Razali et al. \(2014\)](#) experimentally investigated the LVI of two types of glass fibres, namely C glass and G glass fibre, and the fabricated glass fibre epoxy composites were analysed with varying impact energies. It was concluded that the C glass fibre composites absorbed more energy than the G glass fibre composites. A comparison was made between Basalt fibre and glass fibre reinforced Bisphenol-A epoxy based vinylester matrix composites, as prepared by [Sfarra et al. \(2013\)](#) using resin transfer moulding techniques. NDT techniques, e.g., Square Pulse Thermography (SPT), were used to inspect the specimens. It was observed that the impact damage resistance of the basalt fibre composite was superior to that of the glass fibre composite. At higher impact energies, delamination in the glass fibre composites and fibre breakage in the basalt fibre composites are the predominant failures in the composites. These suggest that hybrids of basalt/glass fibre composites can overcome the delamination and fibre breakage in the composites. They also suggest that varying the stacking sequence of the basalt/glass fibre composites is a good way forward.

[Whisler and Kim \(2012\)](#) examined the influence of impact radius on the LVI of glass/epoxy composites. Three types of hardened hemispherical steel impactor were used (radii of 12.7, 50.8, and 152.4 mm). It was observed that the larger radius impactor required more energy to produce damage in the composites. An impactor of radius 152.4 mm required 1.7–4.8 times more energy to initiate damage compared to the 12.7 mm radius impactor. The thicker composites were affected less than the thinner composites by increasing the tip radius due to the contact area of the impactor.

The stitching of the fibre is a new and promising area to strengthen the fibre further. [Bilisik and Yolacan \(2014\)](#) developed 2D stitched glass fibre composites to study the effect of stitching the fibres. They developed the following composites: 1–4 directional hands stitched, 1–4 directional machines stitched and unstitched polyester composites. It was observed that the front and back face area damage of the 2D multi-stitched composites was smaller than for the 2D unstitched composites. When the stitching density increased and the stitching direction increased, the front and back area damage decreased.

[Hadi and Khaleel \(2015\)](#) studied the effect of LVI on a composite plate with and without holes. Experimental work included the manufacturing of an E-glass fibre reinforced polyester composite plate. It was concluded that the presence of holes decreases

the natural frequencies of the composite plate, and absorbed energies and impact force, while the displacement of the composite plate was increased by increasing the number and diameters of the holes.

Naik *et al.* (2000) and Naik and Meduri (2001) investigated the LVI of plain weave glass fibre reinforced epoxy composites with varying levels of impact energies. It was found that the damage tolerance was superior for the low mass and higher velocity combinations when compared to the high mass and low velocity combinations. Reghunath *et al.* (2015) studied the impact resistance of glass fibre composites with different volume fractions of glass fibre and carried out at different impact velocities. This revealed that 43% of the glass fibre composites showed better impact resistance than other composites.

Effect of Temperature on LVI

Composite materials are widely used in the aerospace and space engineering fields in many structural components. Such materials should be surveyed in different environmental conditions, *e.g.*, temperature, pressure etc. For that purpose, Khashaba and Othman (2017) examined the damage resistance of a woven CFRP epoxy composite in varying temperatures, *e.g.*, room temperature, 50°C and 75°C. Compression after impact is also taken into consideration to measure the residual strength. At a higher temperature (75°C), there is no penetration due to the softening of the plasticization of the epoxy matrix. Debonding was observed at the fibre and matrix interface, and also increases in the interfacial stress concentration of the re-solidified matrix were observed. Similarly, Dhakal *et al.* (2014) explored the influence of temperature on the LVI of jute fibre reinforced UP composites. They conducted testing at 30, 50, and 75°C with impact velocities of 1.5 and 2 m/s. The results showed that the jute fibre composites had a maximum load carrying capacity at 30°C.

Consequently, during the bending tests (flexural strength after impact (FAI)), when increasing the testing temperature, there is an extensive reduction in the FAI. A woven-ply carbon fibre reinforced polyphenylene sulfide (CF/PPS) composite was subjected to high temperatures of 95°C and 125°C. A hot pressing technique was used to fabricate the composites with a thickness of 3.72 mm and impact energies of 5, 15, 25 and 35 J. Varying the temperature of the composites highly influenced the impact response, with plastic deformation of the matrix and a coupling effect in the resin rich area and the fibre bridging mechanism (Wang *et al.*, 2018).

Similarly, carbon fibre nanocomposites were studied by Kara *et al.* (2018) at temperature conditions of 23°C, 0°C, – 50°C, – 100°C, – 196°C with an impact energy of 15 J. Multi-walled carbon nanotubes were added into the epoxy composites. At lower temperature, the damage on the composites increased for all the specimens. Moreover, addition of nanoparticles resulted in a higher contact force for the same temperature and there was less damage in the specimens.

Foam Composites Effect on LVI

Foam is the most common form of core material in polymer composites, and has better static and dynamic mechanical properties. Foam is derived from various polymers. Bi-material structures were made from a PLA lattice structure and polyurethane (PU) foam by Koa *et al.* (2018). It was concluded that the flexible foam gave a more positive impact energy absorption than the rigid foams, with a maximum energy absorption of 23% and the proper selection of foam, which enhanced the impact energy of the composites. Likewise, Caliskan and Kemal Apalak (2017) experimentally studied a specimen involving an expanded polystyrene foam core reinforced by an aluminium face sheet using LVI testing and adhesive bonding techniques. LVI testing of foam composites is based on the foam, the foam density and the plate thickness. The lowest permanent deflection and contact force was observed in the highest foam core density and thicker foam core. The energy absorption capacity was increased by increasing the foam core thickness and density. PVC foam has been used as a core material in sandwich composites with epoxy and a polypropylene matrix. Due to the densification of the core material, the response of the structure was changed by increasing the impact energy. Also, the bending stiffness of the thermoplastic composites was lower than that of the thermoset composites, which makes thermoset composites more rigid and stable (Dogan and Arkan, 2017). Woven natural silk/epoxy sandwich composites were prepared by the hand-layup technique and drop weight impact testing was conducted at 32 J. The woven natural silk fibre foam epoxy composites showed better energy absorption than the other sandwich composites prepared. Woven natural silk fibre epoxy core-mat composites possessed enhanced load bearing capacity over the other sandwich composites prepared (Ude *et al.*, 2013).

Bahkoglu *et al.* (2018) investigated the compression after impact behaviour of wooden composites reinforced with pinewood and ashwood as intermediate layers. The composites were manufactured using the VARTM method with 15 and 25 mm thick PVC foams. The energy levels used in this study were 30 J and 60 J, with conical and hemispherical impactors. The pinewood and ashwood intermediate layers increased the residual compression after impact strength and decreased the impact damage depth.

Nano-Composites Effect on LVI

Nano-particle inclusion in the polymer composites enhanced the property of the materials. Many researchers infuse different nano-particles in polymer matrix composites to gain the advantages of the nano-particle. Sonication is the best way to disperse the nano-particle into the polymer matrix to achieve the uniform distribution of the nano-particles. Nanomer organically modified montmorillonite nanoclay was dispersed into an epoxy matrix in a wt% ranging from 1% to 3%. This modified epoxy matrix was

used to fabricate a 15-layer plain weave carbon fibre composite using VARTM. The LVI response was tested for three energy levels. The infusion of nanoclay into the composites reduced the damage due to the increased stiffness and damage resistance (Hosur *et al.*, 2007).

Castellanos *et al.* (2017) investigated the enhancement of the LVI strength of ZnO nano-wires on dry woven carbon fabric layers. To protect against damage in the layered composites, ZnO nano-wire was added into the interlaminar regions. These composites were fabricated with 16 layers of dry fabric with a vinyl ester matrix by the VARTM process. The ZnO nano-wire reinforced composites exhibited lower damage when compared to those without ZnO nano-wire. Also, it was observed that there was an increase in the impact peak load and a reduction in the deflection between cases with and without nano-wire reinforcements. The functionalised multi-wall carbon nanotube (MWCNT) material was added in different weight percentages, *e.g.*, 0.5%, 1% and 1.5%, into the woven carbon fibre composites to increase the impact strength of the composites. The addition of 1.5% MWCNT resulted in a 50% increase in energy absorption and damage size (Soliman *et al.*, 2012).

Carbon nanofillers are other promising fillers for enhancing a material's properties. A carbon nanofiller has been infused into GFRP polyester matrix composites using VARTM in the range of 0.1–0.3 wt%. With the inclusion of the carbon nanofiller in the polyester composites, there was a decrease in the absorbed energy. The wt% of 0.2 carbon nanofillers gave the highest peak load and the lowest energy absorptions compared to conventional composites. The lowest energy absorption was due to delamination, matrix cracking, fibre fracture or pull-out, fibre-matrix debonding and back-face fibre fracture followed by penetration. For all the cases at 30 J, there was clear penetration. However, the addition of nanofillers reduced the delamination in the composites (Tita *et al.*, 2008). To improve the LVI characterization of the composites, a nanoclay and graphene were added into Kevlar fibre-reinforced Epoxy (KE) composites by Rahmana *et al.* (2018). The fillers were added up to 10 wt% with 16 ply KE composites. It was found that the nanoclay (NC) is more effective than graphene (G) for impact resistance and the absorption of impact energy. Also, an NC composite has a better preventing capability than G composites with regards to penetration.

Fibre Metal Laminate Composites – Effect on LVI

The cost effectiveness of the composite structure is increased when using aluminium alloy in fibre reinforced composites. But there are disadvantages with these materials, *e.g.*, the fatigue of the aluminium alloy, and the poor impact and residual strength of carbon fibre composites. Combining these two materials to make hybrid composites can overcome the disadvantages of the materials (Vogelansang and Vlot, 2000; Sinmazçelik *et al.*, 2011). The influence of the carbon fibre orientation in aluminium metal laminates was studied with varying carbon fibre arrangements in the form of Al/(04)/Al, Al/(02,902)/Al, Al/(0902,0)/Al, Al/(0,90,0,90)/Al and Al/(0,±45,90)/Al (subscript 2 – 2 layers, 4 – 4 layers). The energy absorption of the composite was calculated as in Eq. (1) (ASTM D7136/D7136M-15, 2015):

$$E = \frac{m(v_i^2 - v^2)}{2} + mg\delta \quad (1)$$

where,

δ – Indenter displacement (m),

v_i – Initial velocity of the impactor body (m/s),

v – Final velocity (m/s),

m – Mass of the indenter (kg),

g – Gravitational acceleration, 9.81 m/s².

It was observed that the fibre orientation and changing the number of interfaces had no obvious influence on the shape and size of the delamination in carbon aluminium metal laminate composites, and fibre failure was dominant in AlC composites under impact. A crack at the bottom aluminium layer propagated in a perpendicular manner to the direction of the carbon fibre of the adjacent layers (Jakubczak *et al.*, 2017). Similarly, Ferrante *et al.* (2016) studied the LVI of basalt aluminium metal laminate composites with two different impactors: hemispherical and an ogival. It was confirmed that the cause of the damage was delamination between the basalt layers and the aluminium foils.

Glass-reinforced aluminium laminate (GLARE) is the popular hybrid composite in aerospace structure applications. A GLARE composite was fabricated with Nylon 6, 6 nanofibre non-woven mats by the electro-spinning technique and interleaved between aluminium sheets and glass fibre. The Nylon 6, 6 nanofibres showed lower debonding length and reduced the outer damage area by 62% (Zarei *et al.*, 2017). In the same way, two types of FML composite were prepared by Sadighi *et al.* (2017): 3 layers of aluminium alloy sheet with one core glass fibre and epoxy prepreg and another composite, 3 layers of aluminium alloy sheet with two core glass fibre and epoxy prepreg. LVI testing was conducted with the successive impacts which reduced energy levels. Visual inspection and the ultrasonic C-scan method were used to examine the damage, and the damage caused due to the visible damage without internal and external damage, visible internal damage and external damage. It was concluded that the damage propagation by the consecutive impact energy was negligible.

Low Velocity Impact on Hybrid Composites

Hybrid composites are materials fabricated with two or more constituents to gain the advantages of each of the constituents in the final materials. By making hybrid composites, one can reduce the cost of the materials and increase their strength, as well as making environmentally friendly materials. Many researchers are studying hybrid composites to obtain materials with better properties. Accordingly, Hosur *et al.* (2005) studied the low-velocity impact response of 4 different woven hybrid composites. The hybrid composites were fabricated by vacuum assisted resin moulding using carbon and glass fabric with epoxy resin. It was concluded that there was a considerable improvement in hybrid composites over the carbon/epoxy composites.

3D angle-interlocked Kevlar/basalt reinforced polypropylene composites were prepared by Bandaru *et al.* (2016). Three types of composites was manufactured, namely Kevlar 3D, Basalt 3D and Hybrid 3D, using the vacuum-assisted compression moulding method to manufacture the composites. The energy level for all the composites was set as 120 J. The 3D hybrid composites with basalt yarns for warp reinforcement and Kevlar yarns for weft and binders absorbed 7.67%–48.49% more energy than the 3D homogeneous Kevlar and basalt composites.

To take advantage of the high strength fibres, a hybrid of glass/carbon fibre reinforced epoxy composite was prepared. Eight layers of E-glass fibre and carbon plain weave ($0^\circ/90^\circ$) fibre were stacked in different sequences. The LVI of the hybrid composites was analysed for different energy levels. Carbon fibre as the top and bottom layer helped to reduce the damage size and the deflection of the composites. Thermo-graphical imaging is a kind of non-destructive evaluation which is also used to identify the damage occurring on composites (Hung *et al.*, 2018). Basalt/Kevlar fibre hybrid polypropylene composites were made by the alternative stacking of basalt and Kevlar in each 4 layer, Kevlar layers on the front face and basalt 4 layers on the back face of the composites. The hybridization and stacking sequences increased the impact performance of the composites. The alternative arrangement of the Kevlar and basalt fibre composites absorbed more energy than the remaining composites fabricated (Bandaru *et al.*, 2016). Again, a carbon fibre hybrid with aramid epoxy composite was manufactured using the resin transfer moulding process. A hemispherical impactor was used with a diameter of 12.7 mm at 26.8 J. The results showed that carbon fibre as an impact surface has better performance than other composites. Given the average damage area of the composites, the carbon fibre in the impactor surface performed better than the aramid fibre in the impactor surface (Ying *et al.*, 2016). Hea *et al.* (2018) investigated the impact and post-impact flexural strength of carbon fibre reinforced sandwich hybrid composites. A corrugated core aluminium sheet was used to fabricate the sandwich composites using the hot pressing moulding method. In sandwich composites, the top face plays an important role in the composites; the top face does not suffer a lot at lower impact energy and delamination occurred due to matrix cracking. At higher impact energy, the top face was penetrated completely and failure occurred due to fibre fracture and matrix cracking. The post-impact flexural strength and the residual flexural strength depend on the impact energy and the impact location.

The LVI of shape memory alloy (SMA) hybrid composites was characterised by Rim *et al.* (2011). SMA embedded with conventional composite and non-SMA (graphite/epoxy prepreg composites) composites have been investigated.

The incident impact energy (e) is calculated as follows (Rim *et al.*, 2011):

$$e = mgh \quad (2)$$

where

e = the incident impact energy,

m = the mass of the impactor, and

g = the acceleration due to gravity,

h = the height of the impactor.

It was confirmed that embedding SMA with conventional composites increased the impact energy absorption. Wang *et al.* (2008) investigated the influence of the fibre orientation in 3D woven hybrid composites on the LVI properties; aramid (Kevlar[®] 129), basalt fibres and epoxy resin were used to fabricate the interply hybrid composites. The specific energy absorption of the interply hybrid composites was shown to be higher in the warp and weft directions of the composites than in the intraply hybrid composites due to the layer by layer fracture mode.

The LVI behaviour of basalt/nylon intraply laminate hybrid composites was investigated experimentally. A composite plate was fabricated with different warp and weft fabrics. Varying energy levels were used with a hemispherical impactor. It was observed that the impact resistance of the hybrid composites was extensively affected by the addition of the nylon and basalt fibre content (Dehkordi *et al.*, 2010).

Basalt/glass fibre hybrid composites were fabricated by RTM techniques by varying the stacking sequences in the form of BG-HS (7 layers of glass fibre – core, and 3 layers of basalt fibre – skin), BG-HI (basalt fibre stacked alternatively) and mono-composites of basalt and glass fibre composites. Both the hybrid composites performed better than the mono-composites, and basalt as skin and glass as core performed better than the intercalated BG-HI. Basalt fibre composites showed better energy absorption than glass and BGHS composites (Sarasini *et al.*, 2013). To study the damage resistance of the glass and jute fibre hybrid composites, the specimen was fabricated using the hand-layup technique under light pressure at room temperature. The results revealed that the jute laminates have better impact energy absorption than the hybrid composites. But the damage resistance capability is less than that of the hybrid composites (Ahmed *et al.*, 2007).

Thorssona *et al.* (2018) investigated the behaviour of laminated composites on low velocity edge on impact and the compression after impact of the composites. Different impact energies and impact angles of 0° and 45° and NDT techniques were used.

The impact angle of 0° showed a highly localised event, but for the 45° impact angle, there was a considerable global deformation through bending. The impact damage at 0° angles was shown to be more significant than at 45° angles. In the case of the delamination of the composites, for 0° angles of the tested composites, it was clearly visible but for 45° it was hidden from the naked eye. The materials used, the energy level applied and the impactor used are presented in [Table 1](#).

Numerical Studies of Low Velocity Impact

Numerical modeling is a useful tool for analyzing engineering problems and gives approximate results to reality. Numerical modeling can reduce the number of trials needed for the experimental work, which reduces the cost. Likewise, many researchers are doing their modeling using software as well as a theoretical approach. [Tita et al. \(2008\)](#) performed a failure analysis of carbon epoxy composites using numerical and experimental approaches. It was concluded experimentally that the stacking sequence and the energy level are the influencing parameters. Many failure mechanisms were found, *e.g.*, fibre rupture, matrix cracking and delamination.

Honeycomb structures were prepared with a carbon epoxy sandwich composite by [Chen et al. \(2017\)](#). The study obtained experimental data which was compared with the numerical results, and both were in good agreement. [Tiea et al. \(2018\)](#) investigated experimentally and numerically patch-repaired CFRP laminates of different shapes (circle, square, rhombus, hexagon and octagon patches) and sizes placed on a single side of the parent laminate plates. The damage mechanism and the failure prediction of the composites were obtained using numerical methods. From the results, the circle patch leads to a better repair performance than other combinations in terms of the energy absorption and delamination area. A new type of numerical prediction has been implemented by [Salveti et al. \(2018\)](#). The performance of Olsson's analytical model was matched with the experimental values. The volume fraction and the incidental impact energy of the glass fibre reinforced polyamide composites were analysed. The impactor velocity has significant effects on the impact response and the contact force ([Mars et al., 2018](#)).

The FEA model has been developed for glass fibre composites using ANSYS/AUTODY hydro code. The rebound velocity of the projectile increased with the incidence velocity until penetration started, and it was also found that increasing the projectile velocity meant that the energy absorption of the composites also increased ([Ansaria et al., 2017](#)).

LVI and compression after impact have been investigated numerically by [Soto et al. \(2018\)](#) with special attention being paid to computational efficiency. Numerical study demonstrated that delamination and fibre breakage are the predominant failures in the composites. [Topac et al. \(2017\)](#) examined the LVI of CFRP composites experimentally and numerically. The damage mechanism was studied using high-speed camera imaging and the experimental value was compared with the numerical value. [Long et al. \(2015\)](#) predicted the delamination of composites with 2 types of stacking order, and the ultrasonic C-scan was used to identify the delamination area.

Again, FEM was used for carbon and glass fibre interply hybrid composites with varying impact velocities of 3 m/s, 5 m/s and 7 m/s. The experimental output illustrated that the hybrid composite at mass ratio of 37.63 absorbed more energy than the pure composites and the results are in good agreement ([Yang et al., 2015](#)). [Bienias et al. \(2016\)](#) studied the LVI of aluminium glass fibre laminates using both experimental and numerical approaches. Composites plates were fabricated with a thickness of 1.5–3.5 mm using the autoclave process. The LVI analysis was done at room temperature with impact energies of 10 J and 25 J. The damage to the composites includes the delamination taking place in the composite interlayer and on the metal composite interface, and cracking in the composites and in the lower layers of the metal.

[Kathiresan and Manisekar \(2017\)](#) studied the LVI of glass fibre reinforced polymer composites with varying orientations, *e.g.*, random, woven [0/90] and angle-ply [$\pm 60^\circ$]. Using glass fibre, conical frusta shaped composites were fabricated with a semi-apical angle of 15° – 24° . The FEA model was also used, using ABAQUS software to calculate the collapse behaviour and energy-absorption characteristics of GFRP with similar experimental conditions. 3D carbon fibre epoxy composites were prepared with 11.5 mm thickness. The damaged area and the residual depth of the impacted composites plates were analysed ([Elias et al., 2017](#)).

[Pach et al. \(2017\)](#) experimentally and numerically analysed the ballistic resistance of Carbide, steel and Al_2O_3 with 10 layers of Aramid fibre reinforced styrene-butadiene-styrene (SBS) copolymer hybrid composite shields. The experimental and numerical values are compared. They suggested that in order to improve the weft and warp threads of the aramid fibre, the moulding parameters need to change.

Jute-epoxy, rubber, and jute-epoxy-rubber sandwich composites' ballistic impact have been analysed for the different thicknesses and velocities. It was shown that there was a considerable amount of energy absorption in the rubber composites compared to the jute fibre epoxy composites. The damage area of the composites shows the ductile nature for rubber composites and the brittle nature for jute epoxy composites ([Sangamesha and Kulkarni, 2018](#)).

[Pashmforoush et al. \(2018\)](#) performed an optimization of the stacking sequence of carbon epoxy composites in multi-directional laminated composites under LVI to perform damage analysis experimentally and numerically. The composites were cured in various conditions, *i.e.*, in a vacuum with an autoclave pressure of 0.103 MPa, heated at $5^\circ\text{C}/\text{min}$ to 105°C for 60 min and cooling was performed at $50^\circ\text{C}/\text{min}$ to 65°C . The results showed that the stacking sequences of [90/90/90/0]s and [0/90/90/0]s had the minimum damage under compression, [45/_60/60/45]s and [60/90/0/_45]s had the minimum fibre damage under tension [45/_60/0/90]s and [45/_60/60/45]s had the minimum matrix damage under compression and [45/_45/45/_45]s and [0/90/90/0]s had the minimum matrix damage under tension. [Table 2](#) represents the numerical approach used to analyse the LVI of the composites.

Flax fibre reinforced unsaturated polyester composites were studied with three energy levels nearer to the perforation using a hemispherical steel impactor. LS DYNA was used to study LVI. Both the maximum load and the energy absorption were reduced extensively post-impact ([Dogan and Arikan, 2017](#)). Aramid fibre reinforced polymer composites were prepared with varying geometries, *i.e.*, cylinder, ellipse and sphere. The elliptical sample has the highest energy absorption capability, which was due to

the effective stress transfer and maximum energy absorption capacity; the difference was 17% between the elliptical and cylindrical geometries (Ayten *et al.*, 2016). Glass fibre FML composites were studied by Balkumar *et al.* (2016) numerically. They used Design of Experiments (DOE) for the different data set and numerically the results were compared with the already available literature.

Zhang *et al.* (2015) investigated the LVI and compression after impact of honeycomb sandwich composite panels experimentally and numerically. The honeycomb sandwich panel was fabricated with different face sheet thicknesses. The C scan inspection technique was used to inspect and analyse the damage in the composites and it was observed that thin face sheet thickness sandwich composites had less damage area than the thick face sheet thickness sandwich composites. The compressive damage and shear damage are addressed by testing the three point bending test for the honeycomb damage model.

Recyclability of Fibre Reinforced Polymer Composites

Day by day the applications of fibre reinforced polymer composites increased involved in many industrial applications, automobiles, sports etc. since used polymer more possibility for environmental issues. Another side there is a biggest challenge in recycling these wastes. These wastes can be recycle using different techniques like Mechanical recycling, Pyrolysis, Fluidized-bed process, Micro-wave assisted pyrolysis, Solvolysis etc. it was seen that glass fibre polymer composites the mechanical recycling is most suitable (Oliveux *et al.*, 2015). Pyrolysis recycling is most suitable process for carbon fibre composites. Liu *et al.* (2017) reviewed the research papers and found that there is lack of composites recycling workshop and lack of optimization mathematical model to predict the parameters which are influencing the environmental issues. Recycling required the suitable method, work-force, and research plan optimization operations. Asmatulu *et al.* (2014) reviewed the structural composites recycling is important aspects since most of the industries are using composites for structural applications. Ribeiro *et al.* (2016) reviewed the different recycling techniques and advised that the recycling concept need to be improved.

Conclusion

This review has focused on single fibre composites, hybrid composites and metal laminate composites and their low velocity impact properties. The low velocity impact analysis was concerned with the development of new materials for structural applications in the automobile and aerospace industries. Different aspects of the parameters are taken into account for the betterment of LVI in terms of the fibre, matrix, fillers, metal laminates, nano-particles, energy levels, failure, mechanisms, and numerical approach etc. This review concludes with the following:

- (1) Proper selection of the fibre can produce enrichment of the LVI. High strength synthetic fibre is always a better choice for the ballistic nature of the applications. The failures of the single fibre composites are due to the fibre breakage, delamination and matrix fracture.
- (2) Aluminium metal laminate composites are a promising alternative to high strength fibre. In metal laminate composites, interfacial bonding is the key issue, meaning that delamination is the predominant failure mode in composites.
- (3) Nano-particle reinforcement in a polymer composite helps to improve the low velocity impact strength.
- (4) From an environmental perspective, reducing the usage of synthetic fibres in composites means that many researchers have focused on hybrids of natural–synthetic fibres. The stacking sequence and volume fraction of the constituent material enhance the material's properties.
- (5) The numerical approach is an alternative tool to performing the LVI analysis of the composites. Finite element methods are commonly used, and for simulation ABAQUS explicit and ANSYS is used. Almost all of the researchers checked their numerical results with the experimental values.
- (6) For recyclability aspect of polymer composites essential to establish the standard method to recycle the composite waste properly.

Introduction

The ongoing efforts of engineers and scientist in materials and their processing results in development of new material types and/or an improvement in the properties or processing of existing materials. The natural desire for improvement and/or the need to fulfill a task always leads to emergence of new materials or process improvement with an aim to better the performance of an existing system or build a totally new system. As is the process, new materials bring new challenges for the entire spectrum, that is, from basic morphology, characterization, manufacturing, sustainability, recycling until disposal. All of these create new opportunities for design, manufacturing, fabrication, assembly, maintenance, etc. as well as expose the limitations of new developments posing new challenges for research and development. Such an interrelated process is highly instrumental in the development of host of manmade materials (materials that do not exist in nature and are developed by manipulating one or more materials) including the development and application of elastomers. According to ISO (1382:1996), elastomers are *high molar mass material which when deformed at room temperature reverts quickly to nearly original size and form when the load causing the deformation has been removed*. The term elastomer originates from two terms, *elastic*, meaning the ability of a material to return to its original shape upon load removal, and *-mer* from polymer, which means parts. It consists of chains of units and each unit is called a “mer.” Each chain consists of large number of “mers.” These “mers” are linked or polymerized together to construct the elastomer. Each “mer” is usually made of carbon, hydrogen, oxygen, and/or silicon. These are amorphous polymers existing above their glass transition temperature, so that considerable segmental motion is possible. The molecular structure of elastomer consists of *mer* chains, which are cross-linked with each other. Elastomers are derived from many sources but only natural rubber is extracted from the rubber tree (organic production). All other types of elastomers are composed of a wide variety of minerals, which are subjected to polymerization process, the linking together of molecules to create the properties and texture commonly associated with rubber, before it can be used commercially.

Fundamentally, an elastomer is a rubber like polymer, which is both viscous and elastic by nature. In other words, the elastomers have low Young's modulus of elasticity and high strain at fracture/break as compared with other materials. Under application of forces, elastomers conform to large deformation by breaking of intermolecular but without the breaking of covalent bonds of the compound, primarily made of five major elements, that is, carbon, oxygen, nitrogen, silicon, and hydrogen. All elastomers are affected when exposed to different types of fluids. Swelling occurs due to absorption of appropriate fluid, resulting in a volume increase. The degree of swelling depends on the type of base elastomer and the type of fluid that is exposed to base elastomer. It can be as low as negligible and as high as a few hundred percent. When the degree of swelling is substantial, it is termed as a swellable elastomer, else it is known as inert elastomer. In short, a swelling elastomer is a viscoelastic material that swells when placed in certain fluids. The swelling fluid can be fresh water, water with different percent salinity, oil of various grades, a mixture of oil and water, acid, and gas. Water swelling elastomers consist of a base elastomer mixed with hydrophilic filler or swell in water themselves such as hydrophilic polyurethanes.

The application of elastomer spans a wide spectrum including but not limited to automotive, steel, renewable energies, oil and gas, material handling, mining, etc. Recent innovative use of elastomers in defense applications opened another research avenue (Wood, 2018). The self-healing effect of an elastomer due to the local heating helped in closing the fracture surface (Varley and Zwaag, 2010). Thermoplastic elastomer is used in many medical devices due to their recyclability, sterilizability, low level of extractable compounds, and cost effectiveness. The elastomer has successfully found a wide range of applications in the oil and gas industry such as seals due to its high elasticity characteristics, zonal isolation under normal and HP/HT (high pressure/high temperature) conditions, assistance in improving well yield, belts for transmission system, flexible hoses, expansion joints, personal protective apparatus, etc. (Falco, 2000). The use of them as dampers has also made significant inroads in multitude of applications particularly in offshore platform structures. However, the use of swellable elastomer as sealant in nontypical environments, which exist in surface and subsurface conditions, has attracted the attention of the oil and gas industry. The importance of these rubbers can be judged from the fact that global revenues are forecast to rise to US\$56 billion in 2020 (Ceresana Market Research, 2013).

Elastomers in Petroleum Industry

For years, the conventional or multiple casing string technology has been used in the petroleum industry to drill oil and gas wells. The conventional drilling requires current section of the pipe to go through the previous pipe section, which continues until the target depth is achieved. This means that with each section, there will be a reduction in pipe diameter compared with the previous one, which results in loss of internal diameter from the surface to the total depth. These diameter reductions are typically large, for example, a surface hole of 36-in. diameter results in 4-in. diameter at the final depth of the well. These so-called telescopic wells

limit the reachable depth and hence prevent accessibility to deeper reservoirs. The limits imposed by loss of inner diameter on exploration and production of hydrocarbons are not only a mere inconvenience but also results in loss of reservoirs. The development of solid expandable technology (Filippov *et al.*, 1999) enabled the industry to design and build slim wells by significantly reducing the loss of reservoirs as well as premature abandonment of wells due to the unrepairable damages (Pervez *et al.*, 2008, 2007; Seibi *et al.*, 2009; Blasingame and Cales, 2003).

However, with every new development new problems surface. As the well becomes deeper, the seepage of fluids from fractures in the formation and flow of waters in specific zones or the reservoir itself causes many problems in the wells. In particular, when a well experiences aging, unwanted fluids start flowing through the perforations in the pipe. In fractured carbonate reservoirs, the problem arises in cementing due to heavy losses in the circulation material, adjacent to reservoir zones that are subjected to different development scheme such as water flood, gas/oil gravity drainage, and steam or polymer injection, which are critically needed for isolation of undesirable zones (Kleverlaan *et al.*, 2005). Besides all these, water influx causes many difficulties for reaching deep and faraway targets in drilling process and affects the stability of the hole (i.e., creating unstable formations) since it makes the formation over or under pressurized conditions.

All these problems, when combined, result in reduction of oil production, as water seeps inside the production pipe. The resulting effect is more production of water as compared with the hydrocarbon. The energy required to lift this undesired water, separating it from oil/water mixture and later disposal of the separated water adds cost of produced water disposal, treatment against corrosion, and complying with environmental regulations. At times, it has resulted in shutdown of a well due to high ratio of undesired water to hydrocarbon ratio.

Zonal Isolation

The phenomena of shutting of fractured reservoirs producing unwanted fluids or repairing a damaged well pipe fall are the most demanding challenges faced by hydrocarbon producers. Zonal isolation refers to the condition or situation with which the fluid in one permeable zone can be kept separable from those fluids of another zones. The main functions of zonal isolation systems are to shut off water in the permeable zone and divide the well in segments. This segmentation enables for corrective action after water or other fluids break through in one of the segments. Technologies have been developed to design the sheath in an oil/gas well to effectively isolate problematic zones or repair damaged wells using cement slurry, mechanical packers, or swellable elastomers. There are various conventional and new methods for zonal isolation. A brief description of these methods follows in subsequent sections.

Cement liners

Oil well cement is used for zonal isolation and inflow control. The cement is used to seal the annulus between the pipe and the formation wall to prevent mixing between various fluid layers and the migration of gases. However, a series of disadvantages is involved in using cement. Namely, cement shrinks on its setting or environment; it becomes brittle after hardening, and it has unpredictable setting times, thus it can put tools or even the entire well at high risk. Besides that, repairing of a failed cement job is extremely difficult and costly. Cement seals off all zones containing oil and subsequently needs perforation. Fig. 1 shows the consequence of poor cementing, that is, perforations.

External casing packers

External casing packers (ECPs) are considered as one of the mechanical isolation methods. They are short rubber packers inflated by cement as shown in Fig. 2. ECPs work by inflating them during the installation process. For long-term applications, it requires

Fig. 1 Wellbore schematic with consequence of poor cementing. Reproduced from Laws, M.S., Fraser, J.E., Soek, H.F., Carter, N., 2006. PDO's proactive approach to solving a zonal isolation challenge in Harweel HP wells using swell packers. In: Proceedings of the IADC/SPE Asia Pacific Drilling Technology Conference and Exhibition, SPE 100361. Bangkok, Thailand, 13–15 November 2006.

Fig. 2 Use of ECP to shut off fractured carbonate reservoir. Reproduced from Marketz, F., van Noort, R.H.J., Baaijens, M.N., 2004. Expandable tubular completion for carbonate reservoirs. In: Proceedings of the 11th Abu Dhabi International Petroleum Exhibition and Conference, SPE 88736. Abu Dhabi, UAE, 10–13 October 2004.

cement inflation to minimize adverse effects on the packers. If the wells have high deviation or turn to horizontal wells then installation process becomes very complex due to cement inflation. When external casing packers are used for sealing in a permeable formation, some fluids will bypass the rubber element through the pores in the formation. This adversely affects the effectiveness of the packers. In addition, use of ECPs reduces the diameter of the borehole, and the installation involves pumping cement; consequently a cleanout trip is needed (Coronado *et al.*, 2002).

Chemical shutoff

In simple words, chemical shutoff means to shut off zones with gel, where gels and polymer can be placed deeper into the formation (Welling *et al.*, 2007). However, it is also a costly method and in some cases not considered as an efficient way to achieve perfect zonal isolation.

Swellable elastomers

The flexibility in adjusting the material properties (Young's modulus and the compressibility) of swellable elastomers under different temperature, pressure, and working fluids helped to enhance the effectiveness of zonal isolation. During the last two decades, field data showed stress corrosion cracking failures of oilfield pipes and completion-tool equipment. Studies have been done in the laboratory to understand the interaction of heavy brines with commonly used metallurgical alloys in service tools, work string materials, and others. It was found that amine compounds destroy elastomer seals in heavy brine at elevated temperature. Silverman *et al.* (2003) conducted tests for North Sea wells and found that NBR packing and FKM O-ring seals rapidly lose their elongation at break (embrittlement). Elastomer seals made of FEPM Aflas seals remained flexible and elastic in this harsh environment. A comparison between various types of packers is shown in Table 1.

Swell Fix has developed a series of products called a Zonal inflow profiler (ZIP) system, which is one of the new technologies in oil well fields that has helped in solving many resolved problems. The ZIP system has various six combinations, that is, I-ZIP, E-ZIP, X-ZIP, S-ZIP, C-ZIP, and G-ZIP, all of which are based on same work principle (Vliegthart, 2008). ZIP systems have many advantages:

- (1) they provide immediate fracture shutoff,
- (2) they incur less operating cost,
- (3) they have a quick response (less oil loss),
- (4) they make it possible to log and see the flow from each section,
- (5) they have a self-activating mechanism and maintain zones out of water.

Swellable Packers

Swellable packers are made of elastomers that are elastic materials, and significantly swell when exposed to various types of fluids such as saline water, oil, acid, or gas. The two commonly used types are water-swellable or oil-swellable elastomers. Typically, a water-swellable elastomer works on the principle of diffusion and osmosis, and operates in temperature range of 50–90°C. While the oil-swellable elastomers works on the principle of diffusion with a temperature range of 80–130°C. When a wellbore fluid comes in contact with the elastomer, swelling starts due to the process of absorption. Because of absorption, the rubber molecules stretch from low to very high volume. This swelling effect can cause a 600% increase in its volume and over 100% change in its original thickness. Fig. 3 shows an elastomer before and after swell, which clearly demonstrates manifold increase in its volume. The challenge is to obtain a high swell ratio with a good pressure sealing capability. The elastomer swelling rate depends on wellbore pressure, temperature, and fluid composition present in the wellbore.

Table 1 Comparison between three zonal isolation techniques

Comparison parameters	Isolation type		
	Cement liners	ECPs	Swellable elastomers
Sealing effectiveness	Good	Low	Good
Reliability	Good	Below average	Good
Cost	High	Average	Low

**Fig. 3** Original and swelled elastomer in saline water.**Fig. 4** Swellable elastomer seal swell to fill the shape of the wellbore.

The main characteristics of swellable elastomers are as follows:

- (1) Throughout the swelling process, the elastomer absorbs swelling fluids from its environment. Therefore, to enable the elastomer to develop pressure and swell completely on the borehole wall, sufficient swelling fluid should be there.
- (2) In low viscosity oil and higher temperature, oil-swellable elastomers swell further and faster. However, if the oil has high viscosity the swelling process becomes very slow.
- (3) It is not possible to fully preswell the elastomer in lighter oil and then maintain this swell in heavier oil.
- (4) In low salinity water and higher temperature, water-elastomers swell further and faster.
- (5) It is not possible to fully preswell the elastomer in less-saline water and then maintain this swell in a more-saline environment.
- (6) In a mixture of oil and water environment, water-swelling elastomers will only react with water and swell as if they were only submersed in water. On the other hand, oil swelling elastomers will only react with oil and swell accordingly.

One of the excellent characteristics of elastomer seals is their ability to fill any wellbore shape or cavity, pits, scratches and deform easily around asperities as shown in [Fig. 4](#). Thus, to ensure effective sealing, the elastomer seal must maintain a contact pressure greater than the fluid pressure in the formation. For water flood wells a combination of swelling and nonswelling elastomer seals have been used to ensure a compromise between maximum seal coverage, provide the capability to perforate between no swelling seals and protect swelling seals with abrasion-resistant and corrosion resistant rubber while running in the hole ([Marketz et al., 2006](#)).

To attain effective swelling using swellable elastomers, it is necessary to have:

- (1) Correct elastomer composition depending on borehole fluid and operating temperature,
- (2) Supply sufficient swelling fluid,
- (3) Proper seal length to prevent any leakage in permeable formations,

Fig. 5 A typical swellable packer for oil-well applications.

- (4) Seal of adequate thickness,
- (5) Correct depth where elastomer seal need to be placed, and
- (6) Sufficient swelling time to allow installation.

In oil and gas wells, swell packer technology consists of standard oilfield pipes with vulcanized elastomers of various lengths spaced at constant or variable interval as shown in Fig. 5. Once the swell packer comes in contact with formation or borehole fluids, the elastomer element swells to form an effective annular seal through thermodynamic absorption process.

The major advantages of the swellable packer are that they eliminate the need for any extra running or setup and have no moving parts. In addition, they swell nicely o fill all the asperities around that place to form a complete seal. The condition of having adequate time to swell can only be considered as a negative aspect of this process. Therefore, it is important to provide enough time to complete the sealing before the section is used for its intended purpose. However, this problem nowadays tends to be fixed; since new types of swelling elastomer are designed to swell as short as a day or even few hours. Another critical factor to be considered is that getting the placement of the packer wrong can obviously have harmful results to the well. Thus, accurate placement of the packer in an appropriate environment is essential to ensure successful outcome.

Characterization of Swellable Elastomers

Performance estimation of swellable elastomers requires material data along with the geometrical parameters, end conditions, operating parameters and constraints, if any. Hence, comprehensive information is needed regarding the response of material under different operating conditions. Since, the application focus is downhole sealing, therefore material data is required for various salinity, temperature, swelling fluid, etc. Different experiments were designed and implemented for characterization of swellable elastomer and their performance evaluation when used as seals in downhole applications. Standard procedures are available to conduct these tests on rubber materials, which are also carefully followed to obtain consistent results. The objective is to follow ASTM standard as much as possible. The tests include hardness, tensile, compression, and swelling behavior. Test temperatures and salinity conditions were selected to imitate actual well conditions in different oil wells. Three different geometries of elastomer samples are used for characterization.

- *Rings*: These samples are used to obtain the modulus of elasticity of the elastomer by measuring their fracture strength and strain in addition to their cross-sectional area and flattened length.
- *Plates*: These samples are used to obtain the swelling amount of the elastomer over several weeks. The swelling is determined by measuring the volume of the plates every week using graduated cylinder and dimensions and comparing it with the initial volume.
- *Disks*: These samples are used to obtain the hardness of the elastomer every week in addition to the change in volume.

These samples, as shown in Fig. 6, are cut from fresh/unused elastomers. A total of 16 jars are used to hold three types of samples (plate, disc, and ring) under one temperature and one salinity condition. Out of these 16 jars, three jars used to hold three plate samples with one plate in each jar, five jars used to hold disk sample with three disks in each jar, and seven jars used to hold ring samples containing five rings in each jar. The process is repeated for various combinations of temperature and salinity. The selected temperatures are 25/30, 50/80, and 97 °C. The water salinity considered for the tests are 0.5%, 12%, and 25%. All samples at 30°C are kept in laboratory room environment. Four ovens are used to hold samples at 50°C, 80°C, and 97°C. Two small ovens are allocated for 50°C temperature, while one big oven is allocated for 80°C and 97°C temperatures. The following paragraphs describe each test type and associated equipment used for conducting the test.

Tensile Test

The objective of the tensile test is to determine the force required to break the specimen along with the stretch or elongation to the breaking point. Such test data is needed to specify the material type as quality control check of materials, and in designing components or systems to withstand given applied force. Since the elastomer is exposed to different temperature and salinity, it also helps to understand and quantify the chemical and thermal exposure effects on itself. Due to the swelling character of the elastomer, the tensile properties will also change with respect to the time over the entire swelling period. To accommodate this,

Fig. 6 Test sample geometries for elastomer characterization.

samples placed in specific environment are picked at regular time interval, such as one per week, and tests were conducted according ASTM standard D412-06a (ASTM D412-06a, 2007). Tests data are then used to obtain Young's modulus of elasticity, ultimate tensile strength, fracture strength and percent elongation (or percent reduction in area), and other tensile properties. Ring samples are used for this test. The apparatus used are typical universal testing machine and extensometer. Tables 1–4 show the results of 14 weeks' test for Young's modulus of elasticity (E), fracture stress (σ_f), and strain (ϵ) at fracture. The results show a variable nature of increase and decrease in the values of E , σ_f , and ϵ for different combinations of temperature and salinity. Separate tests were conducted to obtain stress versus strain diagram of the elastomer at room temperature as shown in Fig. 7. The stress-strain curve is almost linear, which implies that swelling elastomers (because of their peculiar cross-linking and special filler materials) do not behave like normal rubbers that generally exhibit a nonlinear tensile behavior. The average determined values are $E=14.4$ MPa, $S_{ut}=36.5$ MPa and % elongation = 265%.

Hardness Test

The resistance to penetration in an elastomer is measured through hardness. A durometer is used to measure the elastomer's resistance to penetration without any puncture on its surface based on ASTM standard ASTM D2240 (ASTM D2240-05, 2007). A blunt indenter point was pressed onto the elastomer surface against the action of a spring and readings were recorded based on the A scale as used for soft materials. Every week a swelled sample is taken out of the jar and three measurements of hardness are made at different positions on the sample at least 6 mm apart.

The average of three readings is taken for each sample and the process is repeated for 10 weeks for combinations of temperature and salinities. Figs. 8–11 show the variation in hardness over a period of 10 weeks at temperature of 25°C, 50°C, 80°C, and 97°C. From the figures, one can notice that the hardness is maximum at room temperature and it decreases with time for all salinities. However, the maximum hardness occurred when the salinity is high, that is, 25% and it remained so all along the weeks of the test. It decreases as the concentration of solution decreases, which is true due to the fact that diffusion of salt particles will fill the void in the polymer chain resulting in an increase of its resistance to penetration.

What happens to the hardness of an elastomer as it swells can be of significance in determining seal stability after prolonged exposure. Fig. 12 summarizes the change in hardness for disk samples as they swell in salt solutions of various low level concentrations (0.5%–5%). Hardness of the original elastomer samples (before swelling) on the Shore-A scale was around 60. It is interesting to observe that within a day or two of swelling, hardness drastically dropped down to 10–12, 8–9, 6, 5, and 1–2 for solutions of 0.5%, 1%, 1.5%, 3%, and 5% salt concentrations. What happens to seals formed by these very soft swollen elastomers if subjected to high-pressure differentials can be quite interesting.

Swelling Test

As mentioned in previous sections, swelling in elastomers happens due to the diffusion of salt particles, which results in volume increase as well as change on its thickness. The change in volume and thickness is a function of swelling material, temperature, pressure, swelling fluid and solution concentrations, if any. Free swell test is done using disk samples of 11.2 in./28.4 mm diameter and 0.5 in./12.7 mm thickness, and constrained swelling tests are done using plate samples, that is, elastomer of 6 mm thickness mounted on 50 mm × 50 mm steel plates. To keep track of any fast swell during early days, measurements were taken daily exactly at 24-h intervals for the first 10 days, and then on alternate days until 24 days. Volume measurements were done by in-house constructed graduated beaker-cylinder arrangement. Thickness measurements (average of three readings) were carried out using digital Vernier caliper. After measurements, samples were put back into the respective solutions. Readings were the average of three measurements. Considering the application for field conditions at ambient temperature and around 1–2% brine

14	35,814.00	160,386.15	101.10%	50,610.67	541,658.21	163.27%	52,410.67	512,057.60	148.20%

**Fig. 7** Stress-strain curve for HNBR elastomer at room temperature.

concentration, a thorough test scheme is selected for room temperature and five different concentrations, that is, 0.5%, 1%, 1.5%, 3%, and 5%.

Fig. 13 plots the change in volume of disk samples against number of days of swelling in solutions of different salt concentrations. As can be observed, swelling quickly attains a high value during the first 7–10 days (380% in 0.5% solution, 310% in 1% solution, 250% in 1.5% solution, 190% in 3% solution, and 150% in 5% solution) and then increases rather slowly. The maximum volume swelling observed in 0.5%, 1%, 1.5%, 3%, and 5% solutions after a 23-day period is 430%, 350%, 280%, 250%, and 230% respectively.

Fig. 14 summarizes the volume change against time behavior of plate samples. As observed for disks, plate samples also show a rapid increase in swelling during the first 10 days, and then the amount of swelling slows down (170% in 0.5% solution, 125% in 1.5% solution, 80% in 3% solution, and 55% in 5% solution). Only two plates completed swelling periods of over 20 days: 220% swelling in 0.5% solution, and 150% swelling in 1.5% solution. Therefore, disk samples show far more swelling than plate samples; disks are free to swell on all sides while plates are constrained from one side (elastomer glued onto the plate).

Volume change is a good indicator of swelling of the sample. However, when an elastomer is mounted on a pipe (in a cased hole, for example), sealing between the pipe and the casing is actually achieved through swelling in the thickness (radial) direction. It is therefore very important to observe thickness change with swelling time. **Fig. 15** plots the change in thickness of disk samples against number of days of swelling in solutions of different salt concentrations. As can be observed, thickness swelling quickly attains a high value during the first 7–10 days (90% in 0.5% solution, 80% in 1% solution, 70% in 1.5% solution, 60% in 3% solution, and 50% in 5% solution) and then increases rather slowly. The maximum thickness swelling observed in 0.5%, 1%, 1.5%, 3%, and 5% solutions after a 23-day period is 110%, 90%, 85%, 70%, and 65% respectively. **Fig. 16** summarizes the thickness change against time behavior of plate samples. As observed for disks, plate samples also show a rapid increase in thickness swelling during the first 10 days (80% in 0.5% solution, 60% in 1.5% solution, 45% in 3% solution, and 38% in 5% solution), then the amount of swelling slows down. Only two plates completed swelling periods of over 20 days: 95% swelling in 0.5% solution, and 80% swelling in 1.5% solution.

Note that disk samples again show more swelling than plate samples. As mentioned earlier, thickness change gives swelling in only the radial direction, while volume change represents swelling in all six directions. That is why volume-swelling figures are far higher than thickness swelling values. For instance, maximum volume swelling for disk and plate samples was 430% and 220%

when exposed to 0.5% salt solution for 23 days, while maximum thickness swelling for disk and plate samples under the same conditions was only 110% and 95%, respectively.

Compression-Set Test

Compression-set tests were conducted on fresh EPDM elastomers and when kept in saline water for a period of 22 and 70 h. Test standard ASTM D395 method B is followed (ASTM D395-03, 2007). Compression set is defined as the ratio of change in original and final thickness to the change in thickness due to 25% compression as per standard. Fig. 17 shows the variation in % compression-set at three temperatures and 0.6% salinity. Disk samples were put in an in-house built test set-up to measure compression set. Samples were compressed and held in the fixture for the duration as specified in the standard. Upon removal from the fixture, samples were kept at room temperature for 30 min before taking the final measurement to determine the resultant compression (Pervez et al., 2012). It was found that the compression set rises sharply with an increase in temperature. This increase is more dominant when the exposure time is changed from 22 h to 70 h. Hence, when an elastomer is compressed for

Fig. 15 Thickness swelling of disk samples in different salt solutions.

Fig. 16 Thickness swelling of plate samples in different salt solutions.

Fig. 17 Variation in % compression for duration of (a) 22 h and (b) 70 h.

a longer time and/or higher temperature, the permanent deformation set in would be larger. Furthermore, the compression-set values are higher in elastomer exposed to saline water compared with the fresh ones. This happens due to the loss of material elasticity resulting from settling in of salt particles within the polymer chain.

Swellable Elastomers With Expandable Tubulars

Sufficient literatures have already been published on solid expandable tubular and its importance. Here we look at the prospect of using swellable elastomers with expandable tubular to develop an effective seal. The characteristics of an elastomer are an important element in seal design considering the surrounding factors. It is a standard practice that each oilfield wellbore operation requires its own design criteria. The fluctuation in pressure and temperature in different production wellbores sets one of the many

specifications required for designing a viable solution for the seal to work in the targeted zone. These specifications have either direct or indirect influence on the design. The constraints include operating factors inside the wellbore (direct), specifications requirements for material selection and storage conditions (indirect), and the use of the elastomer material and strength data.

Composition of fluids inside the well

Various fluid types are produced in the well. These mainly include water and hydrocarbons (oil or gas). This part is important to be stated, as one needs to know what fluid will be in contact with the elastomer seal. The current problem looks into the issue of water shutoff operations in wellbores. Thus, water is the primary fluid and one must know its chemical and characteristics such as the percentage of salinity, viscosity, etc.

Wellbore temperature and pressure working ranges

The target is to get the widest suitable working temperature and pressure ranges, which act inside the wellbore at specified depth. By knowing these ranges, one can set the design parameters for the seal to withstand such variations within the specified ranges and to accommodate short-term fluctuations outside the ranges. The ideal wellbore operating range is considered here between a maximum temperatures of 80°C to a minimum of 45°C and between a maximum pressure differences of 70 bars to a minimum of 20 bars.

Applied static and dynamic loads on the seal

Due to pressure variance inside the wellbore, as depth increases, the elastomer seal would experience higher magnitudes of loads. When the tubular, around which the swelling elastomer is held, is in motion towards inside the wellbore, dynamic loads are to be distributed around the seal. Thus, the transient dynamic load will originate from the moving component while installation. Similarly, when the tubular is on hold, static loads act on the elastomer based on the wellbore pressure.

Regularity of shutdown cycles and temperature/pressure changes during shutdown

It is important to know how often well shutdowns are attempted, as these operations may lead to changes within the specified ranges of temperature and pressure surrounding the swelling elastomer. To avoid failure of the seal, one has to set a limit on which the elastomer can endure the shutdown.

Storage conditions

A vital issue of the specification process addresses the question of storage conditions and lifetime, which involves the preuse phase of the elastomer. These include an optimal temperature range set by the manufacturers for storing the swelling elastomer. Humidity must be kept normal inside the storage area. High or even very low temperatures cannot be accepted as a storage condition. These may lead to elastomer degradation, making it not suitable for use. To reduce amount of dirt or dust particulates contacting the surface of the elastomer, normally black polythene bags are used to cover the seal. It also helps to block exposure to sunlight. Storing the elastomer in well-shadowed place away from sunlight is necessary, as it prevents the UV rays from penetrating through the elastomer, which if they do, will harden the material. The use of polythene bags is another solution for protecting the seal against these harmful rays. Adding additives to the elastomer, such as UV light absorbers, may minimize the amount of the rays absorbed. It is also important to assure that the elastomer seals on tubulars do not experience unnecessary external loads. These external loads, if prolonged, may deteriorate the elastomer, causing a plastic deformation to the shape and size of the seal. Fig. 18 shows a solid expandable tubular with cascade of seals around it, ready to be used in an oil well.

A finite element model is developed to simulate the sealing behavior of the seal on a tubular as shown in Fig. 18. The well bore diameter is 155.575 mm, tubular outer diameter=114.3 mm, tubular length=11.6 m, length of each elastomer seal segment=200 mm, seal thickness=17–19 mm, space between seals=200 mm, and seals can swell up to 175.26 mm outer diameter. The objective is to have an effective sealing against formations/casing. In other words, this elastomer seals must be able to develop a contact differential pressure greater than the pressure resulting from the well (liquid pressure) against the seal, $\Delta P_{\text{elastomer}} > \Delta P_{\text{well}}$, as shown in Fig. 19. This target, $\Delta P_{\text{elastomer}} > \Delta P_{\text{well}}$, will be achieved if the elastomer seal is compressed in such a way that internal pressure developed in the seal exceeds the differential pressure. In fact, the swellable seal expands to certain limit depending on available space for swell. Further swelling results in compression of the seal. This will result in a development of pressure within the seal. EPDM is the selected material for swelling the elastomer seal. A comprehensive review of its material properties is provided by Boyce and Arruda (2000). Table 6 shows the yield stress versus plastic strain for the tubular material and Table 7 describes properties for all.

Table 7 Input material data used in finite element model

Material type	Material behavior	Input data
Elastomer	Hyperelastic	Uniaxial experimental test data input as nominal stress and nominal strain of the elastomer (Tables 2–5), Poisson's ratio: 0.4–0.495, Arruda–Boyce model in ABAQUS is used to model the material.
Formation	Elastoplastic	Elastic: Young's modulus = 1.9995×10^6 N/mm ² , $\nu = 0.1$, Mohr coulomb plasticity: friction angle = 18°, dilation angle = 15°, cohesion yield stress = 7.51555 MPa, absolute plastic strain = 0.
Tubular	Elastoplastic	API grade L-80 steel, density = 7800 kg/m ³ , elastic: Young's modulus = 2.1×10^{11} Pa, $\nu = 0.3$, plastic: material test data input for yield stress and plastic strain (Table 7).

To create the model and to perform the finite element simulation, the following assumptions have been made:

- (1) There is a perfect bonding between the elastomer seal and tubular.
- (2) Elastomer is a hyper elastic material.
- (3) The simulation is carried out under steady state condition.
- (4) Dynamic effects are negligible.
- (5) The geometry of the model and the loading are considered as axisymmetric elements.
- (6) Formation is modeled as an elastic/plastic material.

In finite element simulation, initially, the maximum swelled thickness of the elastomer seal is considered as a reference point, assuming that the elastomer had expanded to its maximum thickness based on the experimental test data obtained in the laboratory. A uniform load is applied across the tubular length, which is in contact with the elastomer. The forces will cause the seal to compress between the surrounding boundaries, namely the formation and the tubular once it comes in contact with the formation. This will result in forming a normal distribution of contact pressures against the formation across the seal length. The process of seal compression continues until the desired compression of the seal is attained. This compressed thickness represents the magnitude of true swelling of elastomeric seal, once it starts to swell, under different salinity and temperature.

Fig. 20 Variation in contact pressure along the seal.

Fig. 21 Contact pressure against compression ratio at 80°C.

The pressure distribution along the elastomer seal is shown in [Fig. 20](#), which shows that the contact pressure reaches a maximum value at the center of the seal whereas it tends to drop off as it moves towards the ends of the seal. This is as expected since at ends the seal has the freedom to bend and deform perpendicular to the load direction. This bending at the unconstrained seal end will provide relief in contact pressure developed between the seal and formation. The effects of temperature (80°C) on the developed contact pressure have been studied by considering three different values of salt concentrations as shown in [Fig. 21](#). Simulations are done for other temperatures for which the results are not shown but the discussion includes all. In all cases of salinity, the contact pressure increases with an increase in temperature up to 80°C. At temperature higher than 80°C, the contact pressure sharply decreases for 0.6 saline solution. However, for 12% and 25% saline solutions the contact pressure keeps increasing beyond 80°C, with more increase in higher salinity solution. For low salinity, when the elastomer seal is exposed to very high temperatures the rate of diffusion of liquids increases and chemical degradation will accelerate. Therefore, the swelling will be more, that is, higher temperature generate much higher swelling, consequently the elastomer seal will be accompanied by a loss in strength and related properties.

The elastomer becomes so soft and chemical degradation might occur which eventually causes a weakness on the elastomer resulting in a reduction of the elastomer capability to withstand high pressure and rupturing can occur very quickly at low loads. On the other hand, for high salinity solution, the salt particles find a place in the polymer chain due to its swelling and results in maintaining the material rigidity at high temperature. This may be one of the reasons that can justify the increase in seal contact pressure for high salinity solution at high temperatures. Therefore, at high temperature and high saline solutions an increase in elastomer thickness due to swelling has a positive impact in its ability to maintain better seal pressure and reduces the probabilities to have fractures or sudden failures. Ultimately, contact pressure values tend to be close to each other at higher temperatures; a large amount of swelling makes the elastomer softer so that hardness does not change much under different concentrations and this means less variation in tensile properties and so the contact pressure.

[Fig. 22](#) shows a comparison between the three different water salinities at a temperature of 50°C, which is an illustrative representation of four simulations run for different temperatures. [Fig. 23](#) shows the resulting contact pressure against salt concentration for different temperatures. Three different salt concentrations have been studied (0.6%, 12%, and 25%) to investigate the effect of water salinity on the contact pressure while temperature is kept constant each time (25, 50, 80, and 97°C); the results obtained are also tabulated in [Table 8](#).

Fig. 22 Contact pressure against compression ratio at 80°C.

Fig. 23 Variation in contact pressure for different salt concentrations.

At temperatures of 25°C and 80°C, the seal pressure obtained from analysis shows that as the water salinity increases the seal pressure decreases. This was expected since as the salt concentration becomes higher in the solution there will be less swelling on the elastomer and lower swelling in most cases yields lower contact pressure. Although it is known that lower swelling in the elastomer yields higher hardness and better tensile properties of the elastomer, hence the contact pressure is supposed to be higher. However, to certain limit of temperature, for example, 25–80°C, which means certain limit of swelling thickness the elastomer tensile properties can still tolerate the change on the elastomer seal thickness (no significant weakening occur on the structure of the elastomer) and provide the desired contact pressure.

Conversely, fluctuation behavior of the contact pressure takes places at temperature of 50°C. The seal pressure follows fluctuation in tensile properties of the elastomer at this particular temperature. In reality, this result is valid only if we consider that the hardness of the elastomer increases as the salinity of the water increases since the swelling thickness will lower and the tensile properties will increase. Thus, the elastomer seal with low swelling thickness can give high contact pressure.

This result, actually, contradicts with the previous conclusion drawn for the 25°C and 80°C cases. More elastomer material tests need to be done to find out the reasons for these contradictory behaviors. It is also possible to consider this case as an anomalous condition and one can clarify this fact since the tests results show that the tensile properties for swelling elastomers do not always follow the expected trends for usual rubbers. Tensile properties exhibit a fluctuating behavior as there is a two-way transport of brine (from the solution into the elastomer, and from the elastomer into the solution), which causes changes in salt content and cross-link structure inside the elastomer. Thus, this may have a direct effect on the fluctuation, which makes the elastomer behave in an unpredictable way.

At 97°C, also there are fluctuations in the values of seal pressure. This can be realized by observing the behavior of the material tensile property data set that the developed pressure becomes higher as the water salinity increased to about 12% even though the swelling decreases. The reason behind that is as pointed out earlier; at very high temperatures when there is a large amount of swelling, the elastomer loss its hardness and tend to be very soft thereby it loses its ability to achieve a high contact pressure. The drop in pressure at 25% salinity was expected, since definitely when the swelling thickness becomes very small the pressure sealing capabilities will decrease.

Table 8 Values of contact pressure obtained from finite element simulations

Salinity	Contact pressure (bar)			
	25°C	50°C	80°C	97°C
0.6%	6.3	12.4	72	40.5
12%	5.4	23.3	57	63.5
25%	2.8	17.5	36.3	46.67

Renewability of Elastomeric Materials

One of the major questions posed by environmentalists over the use of elastomers is how quickly the elastomers are manufactured and how fast they can be recycled or degrade naturally within an acceptable time frame, or be replenished within a time frame of 10 years or less. Garvin defines renewable materials as those that can be manufactured or generated quickly enough to keep pace with how fast they are used up (Garvin, 2000). Fundamentally, renewable materials are organic and contain carbon. Gelder (2000) points out that renewable materials will have three basic characteristics, that is, they sequester carbon, they burn, and they are biodegradable. It is possible to develop new products with new functionalities by synthesizing atoms and molecules, which would otherwise will not be possible or difficult to achieve in nonrenewable materials.

The elastomers used in the oil and gas industry are selected based on the requirements of flexibility, processability, mechanical and chemical resistance, diffusion, absorption and osmosis, and functionality at medium to high ranges of temperatures and pressures. It has already been explained that in the majority of downhole applications these elastomers are used in vulcanized form. The global consumption of vulcanized elastomers is about 17.2 million tons/year, out of which 40% comes from natural rubber mainly for the aerospace industry. Hence, it is important to think about what to do with these vulcanized elastomers after their productive use in the field. The process of elastomer recovery is difficult, but there are plenty of reasons to work on its recovery or effective disposal, such as material cost reduction, material and mechanical property enhancement, alternate uses of the waste elastomers, and improved process efficiency. If one looks at the entire life cycle of the elastomer from the inception of material to product design and manufacturing, use, recycle, and final disposal, it can be easily classified in three tiers:

Tier 1: Design and develop material and final products,

Tier 2: Recycle to either recover energy or reuse for further product development,

Tier 3: Final disposal.

Legislative restrictions and financial constraints guided by the environmental problems necessitate the demand for research and development of economic and ecological recycling of elastomer (tier 2) or final disposal (tier 3). There are three alternatives for recycling of elastomers (Hanhi *et al.*, 2015). These are:

- (1) Use in another physical form without any further processing, for example, tires are widely used in making pavements by cutting into fine pieces and mixing with cement slurry, sound barriers, polymer mortars, and concretes. This falls in the category of physical reuse. The physical use of the material in granular form is another way of recycling. The use of rubber scrap is very useful in particular manufacturing processes such extrusion, calendaring, molding, and mold flow applications.
- (2) Reclaim material via a proper chemical process. It leads to a different cadre of the same material either with reduced or enhanced properties. The thermal recovery process such as pyrolysis and combustion is also used for reclaiming of elastomeric materials for material reuse.

Another form of recovery is to incinerate the material and recover energy from it. This type of recycling is questionable based on its impact on the environment, complete transformation of material from solid to ash, and the amount of energy generated through this incineration process. Therefore, out of the three recycling methods, the energy recovery method is least effective in terms of economic and environmental aspects, while reuse, either product or material, has the maximum economic and environmental attractiveness.

CERMAT has developed a cost effective method to recycle elastomer, which was a multinational European project focused on developing complete recycling processes for rubber and polyurethane waste, resulting in mass production of recycled low cost elastomeric composites with good noise and vibration damping capabilities. The recycled elastomers were used again in manufacturing chain at low cost. As a result, the companies adopting it became very competitive or remained competitive in the market for the long run. The research work included complete cycle assessment of six different recycling processes including their environmental impact assessment. The recycled elastomeric material obtained through these six cycles showed similar or slightly lower chemical and material properties, which indicates its potential to enter the market with new or similar products.

A closer look at use of swellable elastomers in oil and gas wells reveals that in the majority of applications, the used materials are not recovered to the surface either due to its full deterioration in corrosive environment, particularly the sulfur corrosion, or difficulty in bringing those materials to the surface. Unsuccessful deployment of vulcanized elastomer on pipe/tubulars results in immediate pull out of the pipe to the surface. These elastomers are kept as is for a few days, devulcanized, and processed again to manufacture for lower grade application such as to reduce salinity, etc.

Microbial Production of Polyhydroxyalkanoates From Plant Oils: Renewability and Biodegradability

Fakhrul Ikhma Mohd Fadzil and Takeharu Tsuge, Tokyo Institute of Technology, Yokohama, Japan

© 2020 Elsevier Inc. All rights reserved.

Introduction

The use of petroleum-based plastic materials has contributed to serious environmental problems and is a hot topic discussed globally. The world is currently unable to cope with the environmental degradation arising from existing chain processes associated with the irresponsible use of plastics by global consumers. Global plastic production reached 322 million tonnes in 2015 alone (Gear *et al.*, 2018), and most of these plastics are non-biodegradable, ending their useful lives in landfill sites and the natural environment. For these reasons, the concept of Sustainable Development Goals (SDGs) proposed by the United Nations (UN) has quickly gained worldwide support for its drive toward a healthy and sustainable global economy. Its goal is to solve environmental problems at the most fundamental level and increase consumer responsibility by managing consumption and production.

There have been extensive efforts to develop and use biodegradable polymers such as polyhydroxyalkanoates (PHAs) as alternatives to fossil-derived materials for a wide range of applications (Huschner *et al.*, 2015; Prados and Maicas, 2016). Biodegradable polymers are naturally synthesized by bacteria and offer advantages over conventional plastics such as polypropylene. The ability of PHAs to be degraded naturally in diverse conditions is one of the most commercially attractive aspects that differentiates them from conventional plastics. PHAs are completely degradable under natural conditions and do not liberate toxic compounds. Carbon dioxide and water are the products of PHAs degradation under aerobic conditions, whereas methane is generated in the absence of oxygen. In this regard, PHA production is carbon neutral because the generated carbon dioxide is returned to the environment (Fig. 1).

The rapid development of commercial biotechnology enables plastic production from bio-based renewable resources. In the last few decades, improvements to PHA-producing bacterial strains has been achieved by optimizing the genetic pathway and upregulating the metabolic flux (Budde *et al.*, 2011b; Tappel *et al.*, 2012). Moreover, recent advances in synthetic biology have contributed to higher PHA yields, particularly in synthesizing next-generation biopolymers (Hiroe *et al.*, 2016; Scheel *et al.*, 2016). For example, the use of recombinant microorganisms in the fermentation process facilitates effective PHA production. Of equal importance is the carbon-containing substrate, and the choice of substrate affects the reliability and economics of the fermentation process, especially in large-scale production. Sugars such as glucose, xylose, and fructose are commonly used as a starting raw materials in PHA production (Hiroe *et al.*, 2016; Mizuno *et al.*, 2018). Nevertheless, the fermentation processes developed using sugars have high production costs because of the cost of the raw materials, which accounts for 45% of the total production cost (Kourmentza *et al.*, 2017).

Taking into account the costly raw materials, alternative feedstocks derived from agricultural activities such as glycerol, fatty acids, and plant oils are favorable for the industrialization of PHA production (Koller *et al.*, 2005; Riedel *et al.*, 2014). Among these, plant oils are seen as valuable agricultural commodities and could serve as an effective carbon source for PHA production. The well-known plant oils include canola oil, corn oil, olive oil, palm oil, soybean oil, and sunflower oil. Plant oils are extracted from the plants through cold pressing and the highest oil content is commonly found in the seed. Among all plant oils, palm oil (PO) is seen as an attractive commodity and contributes significantly to the global oil and fat supply. Palm oil plantations are experiencing rapid expansion throughout Southeast Asia, which is the world's largest producer of plant oils. In 2012 alone, the

Fig. 1 Bioproduction of PHA and its biodegradation steps in the natural environment.

palm oil production reached about 55 million tonnes, accounting for over 30% of global plant oil production (Oosterveer, 2015). Growing demand for palm oil is driving the market, particularly because of its use in food processing and the increasing demand for biofuel feedstocks (Mekhilef *et al.*, 2011) and bioenergy (Umar *et al.*, 2013).

There is keen interest in using plant oils in the industrial production of bio-based products, more specifically in PHA synthesis, because of the early use of palm oil as the research model (Majid *et al.*, 1994). Plant oils have greater carbon content than other carbon sources such as glucose, making them as excellent raw materials for high-yield PHA production. Theoretically, the PHA yield obtained by using plant oil as a carbon source is twice that obtained from sugar (i.e., up to one gram of PHA per gram of plant oil). For example, a low PHA yield is obtained when using glucose: 0.3–0.4 g-poly(3-hydroxybutyrate) (PHB)/g-glucose (Akiyama *et al.*, 1992) whereas a high PHA yield is obtained when utilizing plant oil: 0.84 g-PHB/g-palm oil (Budde *et al.*, 2011a). In a different study utilizing soy bean oil as a substrate for culturing *Ralstonia eutropha*, a high PHA yield also was reported: 0.76 g-PHB/g-soybean oil (Kahar *et al.*, 2004). These reports show the potential of plant oils to be used as sustainable resources for efficient PHA production. Further development and extensive research will promote the use of sustainable resources and may eventually reduce the PHA production cost, allowing bio-based plastics to flourish in diverse applications.

Polyhydroxyalkanoates: A Family of Natural Polyesters

Polyhydroxyalkanoates are a family of natural polyesters synthesized by bacteria from renewable resources in the presence of excess carbon and stress-triggering conditions. When bacteria are grown in such environments, water-insoluble inclusion bodies are accumulated and conserved as an energy resource. These energy storage molecules are broken down under carbon starvation conditions by intracellular PHA depolymerases as a mechanism for bacterial survival. The native PHA producing microorganisms are *Aeromonas* sp., *Bacillus megaterium*, *Cupriavidus necator*, *Pseudomonas putida*, and halophiles such as *Halomonas* sp. However, most proof of concept studies have focused on *E. coli* (Kahar *et al.*, 2004; Tappel *et al.*, 2012) or *P. putida* (Ouyang *et al.*, 2007), which are well understood and whose genetic manipulation is well studied. There are two types of PHA depending on the carbon numbers of their monomeric constituents: short-chain length (scl) PHA with 3–5 carbons and the medium-chain length (mcl) PHA containing 6–14 carbons. The general structure of PHA (shown in Fig. 1) contains carbon, hydrogen, and oxygen, with each monomer having a side chain group, R (Fig. 2). Examples of scl-PHAs include poly(3-hydroxybutyrate), PHB; poly(4-hydroxybutyrate), P4HB; and poly(3-hydroxyvalerate), PHV; or the copolymer; poly(3-hydroxybutyrate-co-3-hydroxyvalerate), PHBV. Examples of mcl-PHAs are poly(3-hydroxyhexanoate), PHHx; poly(3-hydroxyoctanoate), PHO; poly(3-hydroxydecanoate), PHD; and poly(3-hydroxydodecanoate), PHDD; or copolymers like poly(3-hydroxyhexanoate-co-3-hydroxyoctanoate), P(3HHx-co-3HO); poly(3-hydroxydecanoate-co-3-hydroxydodecanoate), P(3HD-co-3HDD); as well as copolymers incorporating both scl and mcl monomers; such as poly(3-hydroxybutyrate-co-3-hydroxyhexanoate) PHBHHx. The mentioned PHAs have relevant thermo-plastic properties and have attracted huge commercial interest. Currently, the available PHAs differ greatly in their thermal and mechanical properties. For instance, the hydrophobicity, melting temperature, glass transition temperature, and crystallinity of the PHAs depend entirely on their monomer composition.

PHB was the first PHA to be discovered in 1926 by the French scientist Maurice Lemoigne. It was found as intracellular granules produced by the bacterium *B. megaterium*. Since then, PHB has been the most extensively studied and characterized polymer in the PHA family, and up to 80 wt% of the cell dry weight can be accumulated when grown with a suitable carbon source (Ng *et al.*, 2010; Park and Kim, 2011). PHB possesses several interesting features, such as water insolubility, low oxygen permeability, and optical purity. It is regarded as a highly crystalline polymer because of its stereoregularity. Given its high crystallinity, this causes PHB to become very stiff and brittle, which eventually results in poor mechanical properties. The mechanical properties of isotactic PHB are as follows: Young's modulus, 3.5 GPa; tensile strength, 40 MPa; and elongation at break, 6%. Compared to petroleum-based plastic such as polypropylene, PHB has a higher tensile strength and Young's modulus. The elongation at break of PHB is just 6%, which is extremely low compared to polypropylene (PP) (400%); thus, PHB easily breaks even at low strain. In addition,

Fig. 2 Short-chain length and even-number medium-chain length PHA monomers.

PHB has a melting temperature of 177°C, which is close to its thermal decomposition temperature. At this temperature, the molecular weight of PHB decreases significantly, resulting in difficulties for conventional melt processing. These limitations limit the commercial value of PHB, and, thus, its properties require significant improvement.

The physical and mechanical properties of PHB could be enhanced by increasing the molecular weight. The long polymer chains in high-molecular-weight PHB polymers have greater chain entanglement, making them much stronger and highly resistant towards degradation (Kabe *et al.*, 2012). The ultrahigh-molecular-weight PHB (UHMW-PHB) has been reported to have a tensile strength of up to 3.88 MPa after processing the PHB fiber by annealing and drawing methods (Aoyagi *et al.*, 2003). In another study, bacterial PHB fibers with up to 1.3 GPa tensile strength were successfully produced through combination of cold-drawing and two-step-drawing methods (Iwata *et al.*, 2004).

Another frequently used technique to improve the properties of PHB is copolymerization with other monomers. PHBV is an important scl-PHA copolymer and can be produced via fermentation by co-feeding bacterial cultures with propionic acid as a precursor for 3HV incorporation. PHBV copolymers with a broader range of 3HV content between 6.5 and 40 mol% have been acquired by growing the *Burkholderia sacchari* IPT 189 strain via two-stage cultivation (Rocha *et al.*, 2008). In the first stage, cells are allowed to grow with sucrose, followed by the addition of propionic acid at a low concentration during the PHA accumulation stage. Developments to feeding methods were reported by Shang and co-workers. They employed sequential and simultaneous feeding for the growth of a recombinant *R. eutropha* strain with glucose and valerate. This strain was capable of producing a high 3HV unit fraction of 62.7 mol% (Shang *et al.*, 2008). The incorporation of 3HV slightly improved the mechanical properties of PHB, although there were still many inherent disadvantages such as a low crystallization rate, low nucleation density, large-size spherulites, and secondary crystallization. Because of the lower glass transition temperature of PHBV, the crystallization rate usually remains low, which limits the development of PHBV. Processed PHBV copolymer tends to be sticky during melt extrusion and remains soft even after long cooling times. The addition of nucleating agents may provide a solution to these complexities. They are added to bacterial polyesters to improve the crystallization rate by increasing the nucleation density and reducing the spherulite size. Among the available nucleating agents, boron nitride has been shown to have a significant nucleating effect on the crystallization rate of PHBV. A few studies have reported the effects of boron nitride on polymer crystallization (Kai *et al.*, 2005). Additionally, it was found that reinforced boron nitride PHBV nanocomposites prepared by melt processing have higher thermal stability and improved gas barrier properties (Ten *et al.*, 2010). PHBV can also form blends with other copolyesters, polylactide (PLA), thermoplastic starch, and natural rubbers (Zhang *et al.*, 2014). PHBV has dual properties that combine the mechanical properties of polyethylene (PE) such as elasticity, flexibility, stiffness, and toughness with the chemical properties of biopolyesters (degradability and biocompatibility). These features make them attractive PHAs for consumer applications, notably in the biomedical field.

Another promising copolymer with attractive features is PHBHHx. This polymer comprises scl and mcl-monomers and has unique characteristics. The incorporation of mcl-monomers to the PHB chains makes the copolymer highly elastic and reduces the crystallinity compared to that of neat PHB. The 3HHx monomer fraction greatly contributes to the polymer properties. The alteration to produce PHBHHx with diverse 3HHx content has been extensively studied by growing recombinant bacteria in a medium containing plant oils as a carbon source. One study reported that PHBHHx containing up to 32 mol% 3HHx was produced and improvements were observed in the mechanical properties (Doi *et al.*, 1995). The P(3HB-co-32 mol% 3HHx) polymer has comparable stiffness to low-density polyethylene (LDPE) and high elongation at break of 856%. This remarkable flexibility makes PHBHHx an excellent biomaterial for medical implants and drug delivery systems.

Nevertheless, the existing methods of PHA production presents some difficulties, such as high input cost, low productivity, and lack of process development, which are drawbacks for broader application. In the subsequent section, the use of renewable and inexpensive carbon sources for PHA production is described in detail, focusing, in particular, on the applications of plant oil and fatty acids as feedstocks.

Plant Oils: A Potential Feedstock for PHA Bioproduction

Plant oils and their derivatives represent a renewable resource that has high potential as a chemical feedstock for the bioproduction of new polymers with a variety of structures and functions. They have been extensively utilized for the production of diverse types of PHAs incorporating scl or mcl or scl-mcl monomers. The synthesis of PHA from plant oils has been the subject of green material research for a long time (Table 1). Akiyama first demonstrated the application of corn oil that is rich with polyunsaturated fatty acid for the production of the PHB homopolymer (Akiyama *et al.*, 1992). New strains of *Alcaligenes* sp. were grown in single-stage batch culture by feeding with 3 g/L corn oil. The dry cell mass reached 2.8 g/L with a PHB content of up to 39 wt% after culturing for just 48 h. Other studies have also reported the use of corn oil for PHB and PHBHHx production using *A. eutrophus* H16 and *A. eutrophus* PHB⁴/pJRDEE32d13, respectively (Fukui and Doi, 1998). These strains grew well and accumulated higher PHA content after being subjected to nitrogen-limiting conditions. Relatively large quantities on a dry cell basis were achieved in both cultures (3.6 g/L dry cell), demonstrating the effectiveness and huge potential of corn oil as a carbon source for PHA production.

Moreover, palm-oil-based products have been extensively used to produce various type of PHAs. Palm kernel oil (PKO) is the oil derived from the kernel of the fruit of the oil palm, *Elaeis guineensis*. It is rich in saturated fats, comprising a mixture of medium and long chain fatty acids (Yun *et al.*, 2003). Initially, Tan and co-workers conducted a feasibility assessment of saponified palm kernel oil (SPKO) for growing *P. putida* cultures (Tan *et al.*, 1997). The strategy employed two-stage cultivation for enhanced cell growth in the first 20 h, followed by PHA accumulation in the later stages. The dry cell mass of the harvested biomass reached a maximum of 6.8 g/L with 1.0% w/v SPKO supplementation. The produced PHA accounted for 27 wt% of the dry cell mass and comprised seven

different mcl-monomers with 3HO as the predominant component. In more recent studies, a recombinant *R. eutropha* strain was demonstrated for the production of PHBHHx with higher PHA content in a nitrogen free medium (Loo *et al.*, 2005). However, the low molar fraction of 3HHx (5 mol%) acquired under all conditions is unfavorable and less attractive for commercial use. Later, the *C. necator* PHB4 with PHA synthase from *A. caviae* was used to biosynthesize P(3HB-co-3HV-co-3HHx) terpolymers from PKO (Bhubalan *et al.*, 2008). The highest cell growth and PHA accumulation was acquired using PKO (5 g/L) with sodium valerate (10 g/L) addition after 36 h of cultivation. In a separate study, the wild *C. necator* H16 strain was investigated for the production of P(3HB) and P(3HB-co-3HV) (Lee *et al.*, 2008). Palm kernel oil was added to a nutrient-rich medium at 5 g/L for the production of both PHAs. A mixture of 5 g/L PKO and 5 g/L propionate in the presence of ammonium chloride allowed the synthesis of a high content of the P(3HB-co-3HV) copolymer, up to 90 wt% of the dry cell mass. They found also that the 3HV monomer was incorporated to a much higher extent than those copolymers produced from mixtures of plant oils and valerate used as a 3HV precursor. Thus, the use of palm oil seems to be favorable because of its suitability for supporting various bacteria, as well as its ability to produce a high dry cell mass. This opens up the possibility for reproducible PHA production with different functionalities.

Another relevant plant oil is soybean oil (SBO), which is widely used for effective PHA production. PHA synthase from *Pseudomonas* sp 61-3 (PhaC_{1Ps}) can synthesize the P(3HB-co-3HA) copolymer using *R. eutropha* as a host strain (Tsuge *et al.*, 2009). The recombinant *R. eutropha* grew in a mineral salt medium supplemented with SBO at 20 g/L. Various mutations in the PhaC1 genes were performed and screened for their ability to grow and produce P(3HB-co-3HA) using soybean oil as a carbon source. There were up to 20 mutants exhibiting high PHA production of over 30 wt% and a maximum 57 wt% of dry cell mass. In addition, the use of the *C. necator* H16 strain expressing PHA synthase from *A. caviae* showed good growth ability and superior PHA accumulation, up to 89 wt% of the dry cell mass (Mifune *et al.*, 2010). Despite this, there has been a lack of improvement in the physical properties of the acquired PHBHHx because of the small 3HHx fraction in the polymer chain. Further strategies have, thus, been implemented to incorporate more 3HHx units that will make the resulting polymers more suitable for wider use. In the same study, the 3HHx monomer fraction was enhanced to 9.9 mol% by introducing a mutant PhaC_{Ac} enzyme, PhaC_{Ac} (NSDG), and deleting PhaC_n to depress the supply of 3HB monomer. The cell growth was slightly reduced although the significant incorporation of 3HHx was observed.

Because the use of plant oils competes with food production, non-edible jatropha oil has been suggested as a suitable feedstock for efficient PHA production. Wild-type *C. necator* H16 was used by Ng and co-workers for the production of PHB and PHBV (Ng *et al.*, 2010). The PHB production and cell growth were increased on increasing the jatropha oil dose to 12.5 g/L, indicating its non-toxicity at high concentrations. Under optimal conditions, the culture produced 13.1 g/L dry cell mass and accumulated 87 wt% PHB with supplementation of ammonia (0.54 g/L) as the nitrogen source. The production of PHBV containing as high as 42 mol% 3HV has been achieved by using the similar strain as in the previous PHB production process (Ng *et al.*, 2011). Increasing the sodium valerate concentration gradually increased the 3HV fraction, but this simultaneously decreased the cell growth. This is partly due to the addition of sodium valerate in the initial stage, which somehow has an inhibitory effect on the cells, which cannot tolerate the higher precursor concentration. As the total carbon from jatropha oil and precursor used was set at 9.51 g/L, the cell growth and PHA content were achieved at 6.7 g/L and 76 wt%, respectively. In addition, the production of PHBHHx from jatropha oil as the sole carbon source was demonstrated by using *C. necator* PHB4/pBBREE32d13 expressing the *A. caviae* PHA synthase. Feeding with 10 g/L of jatropha oil produced a dry cell mass and PHA contents 6.7 g/L and 84 wt%, respectively. However, the recombinant strain was only able to incorporate 3 mol% of 3HHx in the copolyester chain.

Another plant oil that holds great potential for PHA production is canola oil. Canola oil is extracted from the canola variety of rapeseed, which is derived from diverse rapeseed cultivars. In a recent study, canola oil has been used as a non-expensive substrate for PHA production (Valdés *et al.*, 2018). The strategy employed two-stage cultivation by growing the recombinant cells first in a medium containing fructose, followed by PHA accumulation by adding canola oil after 18 h. The recombinant *C. necator* H16 expressing heterologous PhaC2 synthase from *P. putida* CA-3 has been used for the production of scl-mcl PHA copolymers. The incorporation of scl-mcl-PHA monomers implies that the overexpressed synthase has a broad substrate specificity. The strategy enhanced the accumulation of intracellular polymer effectively. After cultivation for 30 h, the PHA concentration in the *C. necator* H16 (pMRC03) reached up to 96 wt% of the dry cell mass, which is high for PHA production.

The results presented here show that plant oils are highly promising substrates for the production of diverse PHAs. Despite the improvement in the PHA content obtained at the small scale, the establishment of high-cell-density cultivation is necessary for feasible large-scale processes.

Using fermentation, many strategies can be applied to achieve high biomass production, and fed-batch feeding is one such way. In fed-batch feeding, the substrate is added depending on the cellular response. The simplest method, pH-stat control, is widely used in lab-scale studies because an increase in the pH of the culture indicates the depletion of the available carbon source. Fed-batch *E. coli* using pH-stat control has proven effective for obtaining high density cell cultivation. Many research works have reported the high-cell-density culture obtained by the fermentation process using plant oils as a feedstock for larger scale PHA production (Table 2). The utilization of soybean oil was found to be highly feasible and effective for PHB production. Using wild-type *R. eutropha* H16 and the PHB4/pJRDEE32d13 mutant strain, both cultures grew well in a mineral salt medium (MSM) containing soybean oil in the presence of ammonium chloride (Kahar *et al.*, 2004). Fed-batch cultivation is key to maintaining the optimum carbon and nitrogen concentration for achieving high cell growth and PHA accumulation. This strategy successfully produced dry cells in 118–126 g/L yield with 71–76 wt% PHA. Using the same carbon source, another study reported PHB homopolymer production using *R. eutropha* KCTC 2662 grown in batch and fed-batch culture (Park and Kim, 2011). The supplementation of soybean oil three times at an initial concentration (20 g/L) by fed-batch culturing at 18 and 50 h increased the

Table 2 Strategies to produce PHAs from plant oils in high-cell-density cultivations

Carbon source	PHAs	Strategies	Dry cell wt. (g/L)	Polymer content (wt%)	Reference
Soy bean oil (SBO)	PHB	<i>R. eutropha</i> KCTC 2662 was grown in batch culture containing 20 g/L SBO and fed-batch culture with 20 g/L SBO added three times.	15–32	78–83	Park and Kim (2011)
		<i>C. necator</i> DSM 545 was grown in a mineral medium with 40 g/L SBO. Pulsed feeding of SBO was carried out when the residual SBO concentration reached 5 g/L.	83	81	da Cruz Pradella <i>et al.</i> (2012)
	PHBHHx	<i>R. eutropha</i> TT013ΔfadB1 was grown by feeding with SBO continuously and stepwise feeding of NH ₄ Cl. Phosphorus-limitation was applied to induce PHA production.	52.2 ^a	65.7	Insomphun <i>et al.</i> (2014)
	PHB and PHBHHx	<i>R. eutropha</i> H16 and PHB ⁺ 4/pJRDEE32d13 were grown in mineral salt medium, and SBO was added by fed-batch feeding (20 g/L) to the culture without nitrogen limitation.	118–138	71–76	Kahar <i>et al.</i> (2004)
Corn oil	MCL-PHAs	<i>P. putida</i> KT2442 was grown by the fed-batch method in mineral medium containing hydrolyzed corn oil. Then, 15 g/L was added to the medium when the corn oil was exhausted.	103–109	27.1–28.5	Shang <i>et al.</i> (2008)
Palm oil (PO)	PHBHHx	<i>R. eutropha</i> Re2058/pCB113 was grown by the fed-batch method with, initially, 20 g/L PO, and nitrogen sources (urea or ammonia) were added to increase PHA production.	98–139	70–74	Riedel <i>et al.</i> (2012)
Palm kernel oil (PKO)	PHB	<i>C. necator</i> H16 was grown with PKO as the sole carbon source by intermittent feeding.	160	72	Sato <i>et al.</i> (2013)
	PHBHHx	<i>C. necator</i> strains CNPJN and CNPCN expressing <i>phaC</i> _{Ac} NSDG were grown with PKO in fed-batch fermentation.	111–165	60.8–76.4	Sato <i>et al.</i> (2015)
		<i>C. necator</i> ASBK was grown in mineral medium with butyrate added as a 3-hydroxyhexanoate precursor. The butyrate/PKO ratios (wt./wt.) were 16.7/83.3 and 23.1/76.9.	170–175	76.5–78.6	
		<i>C. necator</i> strains with upregulated <i>PhaJ4</i> genes were grown in modified basal medium. Stepwise fed-batch processing was employed at 5 g/h and then increased to 10 g/h after 24 h.	215 ^b	81 ^{b,c}	

^aThe dry cell weight was calculated from the polymer content and PHA concentration.^bAll strains were produced with almost the same dry cell weight and polymer production.^cPolymer content was calculated from the dry cell weight and PHA concentration.

dry cell mass twofold, but the PHA content was slightly reduced. Although the dry cell mass was much lower, the PHB yield was 0.82 g/g-soybean oil consumed, which is higher than the previously reported by Kahar *et al.* (2004), which were 0.72–0.76 g/g-soybean oil used. In another study, the high-cell-density fed-batch culture of *C. necator* DSM 545 was reported for PHB production (da Cruz Pradella *et al.*, 2012). The culture produced up to 83 g/L biomass concentration with 81 mol% PHA achieved with SBO (40 g/L initial concentration) and subjected to an unlimited carbon source. The PHB yield calculated from utilized SBO showed very high values of 0.85 g/g-soybean oil compared to those previously reported. Using a similar carbon source as above, *R. eutropha* TT013ΔfadB1 has been tested for the production of PHBHHx by deleting the key genes involved in fatty acid β -oxidation (Insomphun *et al.*, 2014). The deletion of β -oxidation gene clusters on chromosome 1 (*fadB1*) significantly improved the 3HHx incorporation (with 15.7 mol% after 96 h cultivation) with fewer effects on cell growth and PHA production. The culture was continuously fed with SBO at 20 g/L by pulsed addition along with the stepwise feeding of NH_4Cl . During the cultivation, phosphorus-limitation was applied to induce the PHA production. It was demonstrated that the defective β -oxidation strain was able to produce the PHBHHx copolymer with a high 3HHx fraction, although the 3HHx fraction detected in PHA was much higher (23.6 mol%) in the early stages of cultivation.

Another common feeding strategy applied for achieving a high-cell-density culture is using a dissolved oxygen (DO)-stat feedback control. This is employed when the dissolved oxygen concentration (DOC) shows a more sensitive response than the pH when the substrate concentration is depleted, especially in the PHA accumulating phase of the fermentation process. DO-stat control has been used to control the feeding rate of corn oil hydrolysate in a fed-batch culture of *P. putida* with phosphate limitation for mcl-PHA production (Shang *et al.*, 2008). When the hydrolyzed corn oil (mainly consisting of linoleic acid and oleic acid) became depleted in the medium, the carbon source was automatically added so that the concentration of corn oil increased to about 15 g/L. This approach was able to produce a dry cell mass and mcl-PHAs contents of up to 109 g/L and 28.5 wt%, respectively. The produced mcl-PHAs predominantly contained 3HO, 3HD, and unsaturated monomers in the copolyester chain.

Strategies such as supplementing cultures with nitrogen during fermentation have been used to produce a high concentration of PHBHHx in fed-batch fermentations (Riedel *et al.*, 2012). Palm oil (PO), which served as the sole carbon source, was directly utilized from the pure stock, and ammonia and urea were supplied as the nitrogen sources. As a result, the maximum cell growth was achieved, yielding 139 g/L, and up to 74 wt% PHA was accumulated on the basis of the total biomass with urea supplementation. The previously prepared *R. eutropha* Re2058/pCB113 strain used in this work also able to grow in the antibiotic free medium. The addition system present in the newly constructed strain was robust in high-cell-density cultures and showed high plasmid maintenance. Thus, this method may serve as an alternative way for retaining the plasmid without antibiotics, thus significantly reducing the cost of the fermentation process.

Other than PO, PKO is also an excellent carbon source for high-cell-density cultivation. Sato and colleagues tested the PHB homopolymer production from PKO using *C. necator* H16 (Sato *et al.*, 2013). The wild-type strain produced 160 g/L dry cell mass with a PHA content accounting for 72 wt% of the dried cell mass. Additionally, the other two *C. necator* strains, CNPJN and CNPCN, expressing *pha*_{CAC} NSDG were also grown with PKO in fed-batch fermentation for producing PHBHHx. The CNPJN culture only produced dry cell and PHA contents of 111 g/L and 60.8 wt%, respectively. Meanwhile the CNPCN culture resulted in up to 165 g/L dry cell mass with 76.4 mol% PHA. The low yield obtained from CNPJN culture is because the CNPJN strain had low plasmid stability caused by the loss of pJRD215NSDG plasmid in high-cell-density culture. On the other hand, the pCUP3NSDG introduced in the CNPCN strain is highly stable and has proven useful for large-scale PHA production. Unfortunately, the 3HHx fraction obtained was very low and did not provide any advantages for consumer applications. In a more recent study, other groups have continued to produce the same copolymer, targeting an increase in the 3HHx fraction (Sato *et al.*, 2015). The first approach involved replacing the native *phaC1* gene located on the chromosomal DNA of *C. necator* H16 by the mutant synthase of *pha*_{CAC} NSDG from *A. caviae*. Subsequently, they also introduced the β -ketothiolase encoded by the *bktB* gene in the PHA-producing strain (regarded as *C. necator* ASBK) to enhance the formation of the 3HHx intermediate and (R)-3HH-CoA was added along with butyrate to the culture medium as a co-substrate. The upregulated *bkt* gene introduced to the *C. necator* ASBK strain successfully yielded a 3HHx fraction of 13 mol% with supplementation in a butyrate to PKO ratio of 23.1/76.9. The strategy was also capable producing as high as 175 g/L dry cell mass with 78.6 mol% PHA. Moreover, the stepwise fed-batch process was initially carried out with 5 g/h of PKO, which was subsequently increased to 10 g/h after 24 h, and this successfully produced a dry cell mass of more than 200 g/L (Arikawa and Matsumoto, 2016). Thus, a highly effective process for cell growth with a high PHA content can be achieved by using a high-cell-density fed-batch culture. Nonetheless, controlling the 3HHx composition remains a significant challenge, especially on a commercial scale when using recombinant strains. In addition, there are difficulties in controlling the 3HHx fraction, which may vary according to the bioreactor size and culture conditions such as the aeration and feeding of the carbon sources.

Fluorescent and non-fluorescent pseudomonads are well known and can also accumulate mcl-PHA when grown on suitable fatty acids. Recently, several strains of pseudomonads such as *P. entomophila* and *P. putida* have been reported in the literature to have this ability (Table 3). Additionally, they are highly tolerant towards high fatty acid feeding concentrations. Because effective carbon feeding is required, the precursor fatty acid was added twice to the *P. putida* KT2442 culture (each 5 g/L) at 12 and 24 h after growth in a nutrient-rich medium (Wang *et al.*, 2011). An exogenous supply of fatty acids serves as an energy source for bacterial growth and provide intermediates for mcl-PHA biosynthesis, which directly involves the degradation of fatty acids via the β -oxidation pathway. Fatty acids enter the β -oxidation pathway in the form of acetyl-CoA and released two carbon units in each degradation cycle (Fig. 3). Two key enzymes, FadA and FadB, are involved in the last two steps of the β -oxidation pathway. To produce mcl-PHAs effectively, the carbon flux must be channeled directly to the PHA biosynthetic pathway by deleting these two enzymes, which will weaken the β -oxidation pathway. The mutant strain *P. putida* KTOY06 with a defective

Table 3 Bioproduction of mcl-PHAs from fatty acids by pseudomonads

<i>P. putida</i> KT2442	Decanoic acid (C10) at 2 g/L twice	mcl-PHA (71.8% 3HD)	1.44	36.7	
	Octanoate (C8) added twice at 5 g/L	mcl-PHA (81.0% 3HO)	4.64	28.9	Chung <i>et al.</i> (2011)
<i>P. entomophila</i> L48	Dodecanoate acid (C12) at 12 g/L	mcl-PHA (44.5% 3HO)	7.80	50.4	
<i>P. entomophila</i> LAC26	Dodecanoate acid (C12) at 12 g/L	mcl-PHA (98.8% 3HDD)	2.70	90.9	
<i>P. entomophila</i> LAC03	Dodecanoate acid (C12) at 12 g/L	mcl-PHA (41.0% 3HD)	9.90	51.9	

**Fig. 3** Biosynthesis of mcl-PHA from plant oils via the β -oxidation pathway. PhaJ; (R)-specific enoyl-CoA hydratase, PhaC; PHA synthase, FadE; acyl-CoA dehydrogenase, FadB; 3-hydroxyacyl-CoA dehydrogenase, FadA; 3-ketoacyl-CoA thiolase, FadJ/FadI; homolog of FadB/FadA.

β -oxidation pathway produced higher 3HD and 3HDD fractions when grown with sodium decanoate and sodium dodecanoate, respectively (Ouyang *et al.*, 2007). Despite this, the deletion of *fadB* and *fadA* genes from the chromosomal DNA was not effective in slowing the β -oxidation. In addition, another strategy demonstrated the use of a *P. putida* KTMQ01 mutant strain with a deletion in PHA polymerase (*phaZ*) (Cai *et al.*, 2009). By removing the bacterial PHA degradation mechanism, the synthesis of higher fraction of the mcl-PHA dominant unit has been achieved. Morphological analysis revealed that the deletion of PHA depolymerases resulted in the PHA granules becoming larger, explaining why the PHA content reached 86.4 wt% of cell mass. Further, a double mutant of the *P. putida* KTOY08 strain derived from *P. putida* KT2442 was grown in various fatty acids (Liu *et al.*, 2011). There were some irregularities observed in the dominant monomers with different added fatty acids. The feeding of tetradecanoic acid to the double mutant culture for example produced mcl-PHA with a high 3-hydroxytetradecanoate (3HTD) fraction of 93.1 mol%. In contrast, dodecanoic acid supplementation resulted in mcl-PHA with the most abundant monomer fractions, and 3HO was the dominant monomer. The engineered metabolic pathways have proven to be beneficial tools for improving mcl-PHA production in *P. putida*. Similarly, β -oxidation blockage was introduced in *P. entomophila* L48 (Chung *et al.*, 2011). The resulting *P. entomophila* LAC26 with *FadA* and *FadB* deletion accumulated over 90 wt% mcl-PHA composed of 99 mol % 3HDD. However, the dry cell mass was greatly reduced because of the growth retardation caused by defective β -oxidation. However, the *P. entomophila* LAC03 strain with *fadB2x* and *fadAx* deletion produced the same PHA yield as same as the wild-type (*P. entomophila* L48), indicating that mutation did not affect the β -oxidation and high cell growth was observed.

There has been an increase in the production of homopolymer mcl-PHAs in the last decade (Table 4). These studies were driven by the resemblance of many structurally related substrates required for mcl-PHA homopolymer biosynthesis, mainly fatty acids. Hence, it is possible to fine-tune the composition of the mcl-PHAs to obtain significant improvements in the thermal and mechanical

Table 4 Microbial production of homopolymer and near homopolymer mcl-PHAs from fatty acids

^aPHHx, poly(3-hydroxyhexanoate); PHHp, poly(3-hydroxyheptanoate); PHO, poly(3-hydroxyoctanoate); PHN, poly(3-hydroxynonanoate); PHD, poly(3-hydroxydecanoate); PHUn, poly(3-hydroxy-10-undecenoate); PHU, poly(3-hydroxyundecanoate); PHDD, poly(3-hydroxydodecanoate); PHTriD, poly(3-hydroxytridecanoate); PHTD, poly(3-hydroxytetradecanoate).

properties. Mutant *P. putida* KTQQ18 was constructed from the previous *P. putida* KTOY08 strain but with an additional deletion in the *fadB* gene, which encodes the β -oxidation complex subunit alpha, and the *phaG* gene, which encodes the 3-hydroxyacyl-CoA-acyl carrier protein transferase (Liu *et al.*, 2011). The resulting strain was able to synthesize PHD homopolymers in the presence of decanoate, yielding 10.6 mol% PHA. In addition, the *P. putida* KTHH03 mutant with a knockout in the *phaG* gene and other β -oxidation-related genes likewise enabled the production of mcl-PHA homopolymers from hexanoate and heptanoate (Wang *et al.*, 2011). Poly(3-hydroxyheptanoate) (PHHp) homopolymer production was as high as 68.9 wt% at 5.32 g/L dry cell mass. However, the production of the PHHx homopolymer was low, and only 21.2 mol% of dry cell mass was achieved. In the same manner, the production of mcl-PHAs from fatty acids in recombinant *E. coli* CAG18496 was achieved by utilizing the *fadB* mutant strain as the host and expressing heterologous biosynthetic enzymes from *P. putida* and *P. aeruginosa* (Sato *et al.*, 2012). The heterologous production system produced mcl-PHAs homopolymers and, to a lesser extent, near homopolymers. The PHA production was over 20 wt% when cells were grown on 2-alkenoic acids with acyl chain lengths from C8 to C10, whereas PHA was inadequately accumulated in the presence of the shorter chain 2-alkenoic acid. Furthermore, the production of mcl-PHA homopolymers from recombinant *E. coli* LSBJ with the elimination of *fadB* and its homolog, *fadJ*, genes from the β -oxidation pathway was studied, where fatty acids were used as the sole carbon source (Tappel *et al.*, 2012). The defective β -oxidation resulted an accumulation of enoyl-CoA intermediates, which were then converted to the corresponding mcl-PHAs by heterologous expression of (R)-specific enoyl-CoA hydratase (PhaJ4) and a broad specificity PHA synthase [PhaC1 (STQK)] from the plasmid DNA. The recombinant *E. coli* production system offers a wider range of mcl-PHAs than the previous work reported in *P. putida*. However, the cell production and PHA yields acquired are much lower than the *Pseudomonas* system developed by Wang and co-workers, suggesting the low intolerance of *E. coli* towards the high concentrations of the fatty acids supplied. To overcome the drawbacks of low PHA yield, Scheel and associates prepared an *arcA*-deleted strain to inhibit the expression of genes involved in β -oxidation along with a *fadR* (the regulatory protein that represses the genes for the β -oxidation pathway and activates unsaturated fatty acid synthesis) mutation (Scheel *et al.*, 2016). Removal of the *arcA* transcriptional regulator in the *E. coli* LSBJ strain had a significant effect on the inhibitive expression of β -oxidation-related genes. The resulting *E. coli* RSC02 strain had improved metabolic flux through the fatty acid

Table 5 Thermal and mechanical properties of mcl-PHAs

Strains	PHA	Melting temperature, T_m (°C)	Glass transition temperature, T_g (°C)	Tensile strength (MPa)	Young modulus (MPa)	Elongation at break (%)	Reference
<i>P. putida</i> KTQQ20	PHD (100% 3HD)	72	−37	12	20	313	Liu <i>et al.</i> (2011)
	PHDD (84% 3HDD)	78	−32	5	103	88	
<i>P. putida</i> KT2442	PHN (70% 3HN)	46	−45	6.6	1.5	1327	Jiang <i>et al.</i> (2012)
	PHN (95% 3HN)	63	−48	15.7	11.3	1317	
	PHO (88% 3HO)	54	−40	9.6	3.4	1384	
	PHO (94% 3HO)	58	−	11.7	4.7	1267	
<i>E. coli</i> LSBJ	PHDD (74% 3HDD)	76	n.d.	10	114	225	Hiroe <i>et al.</i> (2016)
	PHDD (85% 3HDD)	77	n.d.	10	156	161	
	PHDD (99% 3HDD)	82	n.d.	11	180	270	
	PHD (99% 3HD)	70	−46	8	118	226	

catabolic pathway, which eventually increased PHA accumulation. Although PHA production was enhanced, a key challenge related to this fatty acid biosynthetic pathway is in achieving high cell production as well, a crucial factor for an effective production system. Continuing with the previous use of the *E. coli* LSBJ strain, further improvements in PHA production were carried out by the supplementation of sugars as co-carbon sources, which is necessary to promote the production of biomass (Hiroe *et al.*, 2016). Cells were initially grown with glucose supplied at 10 g/L to allow high cell biomass production; then, fatty acids (2 g/L) were added after 6 h to induce PHA production. The two-stage culture strategy achieved up to 3.64 and 4.72 g/L dry cell masses for PHDD and PHHD production, respectively. On the other hand, PHA production remained moderate, and further process development is required to increase the PHA yield. In a more recent study, *P. entomophila* LAC23 (deletion in *fadB*, *fadA*, and *PSEEN 0664* genes) has been demonstrated for producing mcl-PHA with chain lengths from C7 to C14. The highest PHA yield was obtained with 12 g/L sodium decanoate and accumulated over 90 wt% PHA consisting of 99.6 mol% 3HD.

Table 5 presents the thermal and mechanical properties of mcl-PHAs produced by *E. coli* and *P. putida* strains. The dominant mcl-PHA monomers play an important role in enhancing the tensile strength and Young's modulus in PHO and poly(3-hydroxy-nonyanoate) PHN (Jiang *et al.*, 2012). Furthermore, the melting temperature, Young's modulus, and elongation at break of the PHDD homopolymer from *E. coli* were, of course, not only higher than those conventional mcl-PHA but also the copolymer itself (Hiroe *et al.*, 2016). This demonstrates the flexibility of the mcl-PHA homopolymers, which could be used as stretchable films. The naturally synthesized mcl-PHA copolymers from pseudomonads are soft but sticky and, thus, difficult to process; however, the homopolymer polyesters are hard elastomers and, thus, have advantages for melt processing. Because mcl-PHA homopolymers are superior to the copolymers, they have a versatile range of thermal and mechanical properties that are desirable for many applications.

Challenges, Future Outlook, and Concluding Remarks

In a challenging global scenario with unstable fossil fuel prices and increasing serious environmental problems, PHA is certainly a promising polymeric material that demands further attention. The exorbitant price of pure chemical feedstocks and use of antibiotics are two major factors increasing the cost of large-scale PHA production. Although many innovative strategies for PHA production have been demonstrated, these methods are still inapplicable for industrial use. Therefore, the use of plant oils as an alternative carbon source is expected to reduce the production costs in more reasonable way. Plant oils and their derivative products are renewable resources, guaranteeing availability for the effective production of PHA. It is expected that the demand for plant oil products will continue to increase as a result of the development of green polymers. Hence, worldwide participation is encouraged to establish an effective supply chain and to increase the output of plant oils to ensure continuous and efficient PHA production at the industrial scale. In addition, the use of plant oils is not driven by the cost and yield alone but also provides versatility for the development of various PHA with broad applications.

From the small- to pilot-scale, PHA production has been demonstrated with the use of recombinant microorganisms in culture suspensions. Nevertheless, there are still several issues related to the PHA-producing strain itself, where plasmid instability may occur in high-cell-density cultures. Additionally, the complexity of the fermentation process such as aeration, substrate feeding rate, inhibition, and stress response, as well as polymer extraction, may also influence the properties of the PHA. More work should be carried out on process development to improve process efficiency further to increase the competitiveness of PHA plastics. An integrated solution for highly efficient and productive strains capable of utilizing cost-effective substrates with an optimized fermentation process will certainly lead to the use of PHA as a sustainable material in the near future.

This review has summarized the recent trends in PHA production from plant oils as a way for diversifying PHAs for broader applications. The strategies involve the genetic modification of microorganisms combined with the use of plant oils to provide a unique type of PHA that cannot be synthesized naturally. The mcl-PHA homopolymers, which are structurally related to the corresponding fatty acids, having similar chain lengths, are novel materials with outstanding properties. In the future, further improvements in the processability and applicability of PHAs for consumer use could increase their use in biodegradable plastics,

food packaging, toiletries, and other consumable products. The sustainability of PHA and its promising applications apply not only to the consumer plastics industry but also biomedical industries.

Natural Fiber Reinforced Composites in the Context of Biodegradability: A Review

Santhosh Kumar S and Somashekhar S Hiremath, Indian Institute of Technology Madras, Chennai, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

The evolution of materials started in 10,000 BCE when the wood and stones were used as tools and weapons. The relative importance of the ceramics, composites, polymers and metals as a function of time and their evolution are presented in Fig. 1. The use of materials begins in Stone Age around 10,000 BCE, when humans began using bone, clay, animal skin, shells, fibers and feathers for making jewelry, weapons, tools and shelter. At the end of the Stone Age metals, polymers, composites and ceramics were used to create the ornaments and tool. The first extraction and use of copper and bronze are roughly estimated between 4000 BCE and 1000 BCE is called the Bronze Age. During this time the use of copper had become very apparent due to their superior properties which allow shaping these materials to any required shape. The period from 1000 BCE to 1620 CE is called the Iron Age. In the year 1620, development of cast iron technology has established the dominance of metals in industries and then the evolution of steels, alloy steels, lightweight and superalloys took place during the 1800–1940 (Ashby, 1987). During this time materials like rubber, glass, cement, refractory materials and glues were also used in many applications but the relative importance for these materials was less as because of the dominance of metals. After the World War II between 1940 and 1945, the major transition has taken place in the development of new materials – lightweight with high strength titanium and zirconium alloys has given new hopes to aerospace, energy and civil construction industries. Also, the development of new metallic alloys and demand for steel and cast iron are fallen down from 1960. After 1970, there is a drastic change in the development of alloy materials like dual phase steels, microalloyed steel, superalloys are seen in the market.

On another hand, the development and demand for polymers, composites and ceramics were growing rapidly from the 1970s. The attractive features of composite materials like lightweight, high specific strength, stronger, harder, stiffer, flexibility in design and ease of tailoring the required properties calls for research attention. The development of new composites and their use still has higher market potential and is projected to increase in future years. Today composite materials have taken 60%–70% of the market due to their superior characteristics as mentioned above. The following section gives an insight on composites, classifications and role of natural composites.

Fig. 1 Schematic of relative importance of the metals, polymers, composites and ceramics as a function of time. Modified from Ashby, M.F., 1987. Technology of the 1990s: Advanced materials and predictive design. Philosophical Transactions of the Royal Society A: Mathematical, Physical and Engineering Sciences 322 (1567), 393–407. doi:10.1098/rsta.1987.0059.

Composite Materials and Classifications

Composite materials are a new class of engineering materials made from two or more constituent's materials that remain separate and distinct on the macroscopic level while forming a single component. Which performs better than those of the individual constituents used independently (Anandjiwala and Blouw, 2007). In contrast to alloy, each material retains its inherent characteristics such as physical, chemical and mechanical properties. It consists of a matrix phase as a continuous phase and the reinforcing phase as a discontinuous phase.

Composites are mainly classified based on the matrix phase such as metal (known as metal matrix composite – MMCs), polymer (known as polymer matrix composites – PMCs) and ceramic (known as ceramic matrix composite – CMCs). Similarly, composites are classified based on reinforced phase such as particulate (known as particulate composites), fiber (known as fiber composites) and structural (Known as structural composites) as detailed in Fig. 2. Detailed constituents of these composites are listed in Table 1.

The constituent materials are selected based on properties requirements for the applications and cost of the materials. Metal matrix, polymer matrix, ceramic matrix and fiber composites are commonly used in most of the industrial, automotive, aerospace, sports and space applications. Although tremendous development in the field of composite materials there has been always in search of new materials which can perform better at affordable costs compared to previous materials and also the developed materials should be biodegradable. The biodegradability of the materials is very important in the current scenario to overcome the problem associated with disposal and most of these materials take more time to decompose. Table 2 shows the life span of various materials that takes to decompose as the time lapses. Natural fibers and related components will takes less than a year to decompose compare to other materials.

At present most of the industries are switching to biodegradable materials due to

- Growing interest in reducing the environmental impact of polymers or non-biodegradable composites due to increased awareness of eco-friendliness (Satyanarayana et al., 2009; Bajpai et al., 2017).
- Finite petroleum resources, decreasing pressures for the dependence on petroleum products with an increasing interest in maximizing the use of renewable materials.
- The availability of improved data on the properties and morphologies of natural materials such as lignocellulosic fibers, through modern instruments at different levels, and a hence better understanding of their structure-property correlations (Satyanarayana et al., 2009).

Fig. 2 Classifications of composite materials.

Table 1 Constituents of different composites and their applications

Sl. No.	Composites	Applications
1	<i>Metal matrix composites</i> Matrix: Aluminum, magnesium, titanium, cobalt, copper etc. Reinforcements: Boron carbide, silicon carbide, alumina, graphite, titanium carbide	Engine cylinder sleeves, piston-recess walls, bearings, brake discs, heat-sinks in electronics, bicycles frames etc.
2	<i>Polymer matrix composites</i> Matrix: Thermoset polymers: Epoxy, polyester, phenolics etc. Thermoplastic polymers: polycarbonate, polyvinyl chloride, nylon, polystyrene, polyethylene etc. Reinforcements: Glass, carbon, aramid fibers etc.	Boat bodies, load-bearing aerospace structures like wings, tennis racquets, bulletproof jacket, canoes, kayaks, automotive parts etc.
3	<i>Ceramic matrix composites</i> Matrix: Silicon carbide, Boron carbide, Alumina oxide Reinforcements: Silicon carbide fibers, alumina fibers, carbon fibers etc.	Heat shield in space vehicles, cutting tool inserts, dies, pressure vessels, jet engines, gas turbines, turbine blades, brake disk etc.
4	<i>Particulate composites</i> Matrix: Cement, elastomeric polymer, epoxy etc. Reinforcements: Aggregates (sand and gravel), ceramics particles, glasses and metal particles, carbon nanotubes etc.	Concrete, sand and water, wood particle board, tire etc.
5	<i>Fiber composites</i> Matrix: Epoxy, phenolic, polyester, vinyl ester etc. Reinforcements: Chopped or continues glass fibers, carbon fibers, hemp fibers, jute fiber, aluminum, aluminum oxide, aluminum silica etc.	Bulletproof vests, landscaping timbers, park benches, window and door frames, indoor furniture
6	<i>Structural composites</i> Matrix: Plastic matrix, face sheet of metals Reinforcements: Metal sheets, cotton, paper, woven glass fibers, foamed polymers, synthetic rubbers, inorganic cement, balsa wood etc.	Roofs, floors, walls of buildings, and in aircraft for wings, fuselage and tailplane skins

Table 2 Life span of material decomposition

Material	Time to degrade in the environment
1. Glass and tires	Uncertain time
2. Plastic	450 years
3. Aluminum can	200–500 years
4. Tin can, Rubber boot sole	50–80 years
5. Painted wood	13 years
6. Natural Composites	
a) Wool stocking	1 year
b) Bamboo stick	1–3 years
c) Cotton, Banana peel, Orange peel,	1–5 months
d) PolyCaprolactone - Grafting - Maleic Anhydride /starch, PolyCaprolactone - starch	2 months
e) Waste Gelatin / Polyvinyl Alcohol, Waste Gelatin / Sugar Cane Bagasse, Conventional copy paper	1 month

Note: Satyanarayana, K.G., Arizaga, G.G.C., Wypych, F., 2009. Biodegradable composites based on lignocellulosic fibers-An overview. Progress in Polymer Science 34 (9), 982–1021. doi:10.1016/j.progpolymsci.2008.12.002.

These factors have greatly increased the understanding and development of new materials such as biocomposites in which the natural fibers are reinforced in natural resins or thermoset/thermoplastic resin. The following Section “Natural Fiber Reinforced Composites” provides an overview of different aspects of natural fiber composites.

Natural Fiber Reinforced Composites

Natural fiber reinforced composites contain reinforcement phase as natural fiber itself they are abundant, renewable, biodegradable, low-density compared with other synthetic materials (Joseph *et al.*, 1999; Akil *et al.*, 2011; Chaudhary *et al.*, 2018b). Some of the commonly used natural fibers are as a reinforcement are rice husk (Wei and Meyer, 2016), henequen (Herrera-Franco and Valadez-González, 2005), banana (Oksman *et al.*, 2009), pineapple, abaca (Cai *et al.*, 2016) sugar cane, birch fibers (Mejri *et al.*, 2018), oil palm, hemp (Dayo *et al.*, 2017), jute (Basak *et al.*, 2018; Chaudhary *et al.*, 2018a,b), sisal (Giridhar *et al.*, 1986; Li *et al.*, 2016; Bajpai *et al.*, 2017), flax (Andersons *et al.*, 2005; Arbelaziz *et al.*, 2006), curaua fibers (Monteiro *et al.*, 2015), Sour-weed (Patel *et al.*, 2018), betel nut (Merajul Haque and Hasan, 2016) etc. The reinforcement is

mixed with the matrix phase – natural resins, thermoset and thermoplastic polymers (Alves *et al.*, 2010) which acts as a binder to form the composites. Natural resin includes wheat starch, corn starch, potato starch, biodegradable polyester, polyacids etc., (Satyanarayana *et al.*, 2009) thermoset polymers include epoxy, polyester, phenolics etc., and thermoplastic polymers include polycarbonate, polyvinyl chloride, nylon, polystyrene, polyethylene etc. (Alves *et al.*, 2010; Ku *et al.*, 2011; Sahari and Sapuan, 2012; Mitra, 2014; Dayo *et al.*, 2017).

Major factors to be considered when the natural fiber is used as reinforcement are thermal stability of fibers, fiber volume fraction, fiber size, orientation, texture, wettability, moisture content and humidity (Yallew, 2015). The biodegradability of plant fibers can contribute to a healthy ecosystem while their low cost and high performance fulfill the economic interest of the industry. When natural fiber-reinforced plastics are subjected, at the end of their life cycle, to combustion process or landfill, the released amount of CO₂ of the fibers is neutral with respect to the assimilated amount during their growth (Wambua *et al.*, 2003; Thakur, 2013; Merajul Haque and Hasan, 2016). Synthetic fibers such as glass, carbon and aramid reinforced with polymer matrix materials provide advantages of high stiffness and strength to weight ratio in many applications as compared to conventional construction materials. In spite of these advantages, researchers are trying to develop natural composites as because the widespread use of synthetic fiber-reinforced polymer composite has a tendency to decline because of their high-initial costs. Another major drawback is the production of synthetic composites requires a large quantum of energy and quality of environment suffered because of the pollution generated during the production and recycling of these synthetic materials. Natural fibers are classified into three groups plant fibers, animal fibers and mineral fibers. Fig. 3 shows the classifications of natural fibers.

Fig. 3 Classifications of natural fibers. Modified from Mohanty, A.K., Misra, M., Drzal, T., 2005. Natural Fibers, Biopolymers, and Biocomposites, first ed. CRC Press, Taylor and Francis group. Riedel, U., Nickel, J., 2005. Applications of Natural Fiber Composites for Constructive Parts in Aerospace, Automobiles, and Other Areas. Weinheim: Biopolymers Online, Wiley-VCH Verlag GmbH & Co. KGaA. doi:10.1002/3527600035.bpola001. Akil, H.M., Omar, M.F., Mazuki, A.A.M., *et al.*, 2011. Kenaf fiber reinforced composites: A review. Materials and Design 32 (8–9), 4107–4121. doi:10.1016/j.matdes.2011.04.008. Pandey, J.K., Nagarajan, V., Mohanty, A.K., Misra, M., 2015. Commercial potential and competitiveness of natural fiber composites. Biocomposites: Design and Mechanical Performance, 1–15. doi:10.1016/B978-1-78242-373-7.00001-9. Hiremath, A., Sridhar, T., 2018. Use of bio-fibers in various practical applications. Reference Module in Materials Science and Materials Engineering, 1–5. doi:10.1016/B978-0-12-803581-8.11116-6.

Plant-based fibers are also known as cellulose fibers which contain mainly cellulose and lignin. Plants, agricultural waste, agro-industrial residues and vegetal substances are major sources of these fibers (Yao *et al.*, 2008). These fibers are further divided into wood fibers and nonwood fibers. Further non wood fibers are categorized as seeds fibers which are extracted from dried seeds of the plant, leaf fibers extracted from leaf, bast fibers extracted from inner bark of a trees, fruits fibers extracted from dried fruits (Joseph *et al.*, 1999), stalk fibers taken from the stalk of a plant and grass fibers. Photographic view of some of the commonly used plant's fibers is shown in Fig. 4(a). Chemical compositions, type of processing techniques, dimensions of the fibers, place of growth and time of harvest are some of the important factors influence the final properties of the natural fibers. Plant-based fibers are commonly used in automotive interior design, construction industries, aerospace interior parts and sports equipment. Largest producers of natural fibers and productions rate are also presented in Table 3. These fibers are reinforced in the natural resin, thermoset and thermoplastic matrix materials to achieve the required shape of the end products and strength.

Animal fibers are another alternative to replace the synthetic fibers which are generally comprised of proteins, examples mohair, wool, silk, alpaca, angora (Cheung *et al.*, 2009). These fibers are generally divided into two categories such as fibers extracted from cocoons – silk fibers and the fibers taken from hairs of animals or hairy mammals. Some of the examples for animal hairs used to manufacture natural composites are sheep's wool, human hair, goat hair, rabbit hair, alpaca hair and horse hair. Feathers and feather fibers collected from birds also reported in the by researchers. Table 4 shows the properties and chemical composition of the different natural fibers. Photographic views of some of the commonly used animal fibers are shown in Fig. 4(b).

Mineral fibers are a third class of natural fibers which are naturally occurring fiber or slightly modified fiber procured from minerals comes from the asbestos group. Some of the mineral fibers are amosite, crocidolite, tremolite, actinolite, anthophyllite, chrysolite. Fig. 4(c) shows the photographic view of some of the commonly used mineral fibers.

There are plenty of research papers are available on natural fiber reinforced composites in which some of the selected literature are listed in Table 5 which gives information on reinforcement and matrix materials used to manufacture the natural fiber composites and important characteristics drawn based on the different test conducted by researchers.

Manufacturing Techniques

Some of the commonly used manufacturing techniques are:

- (1) Hand layup technique
- (2) Compression molding technique
- (3) Vacuum-assisted resin transfer molding technique
- (4) Injection molding technique
- (5) Pultrusion technique

Hand Layup Technique

Hand layup technique (Harish *et al.*, 2009; Kumar *et al.*, 2011; Junior *et al.*, 2010; Ashok Kumar *et al.*, 2010; El-Tayeb, 2008) is most commonly used method for manufacturing the biocomposites from small to the large scale shown in Fig. 5. It is the simplest molding technique and most economical method which can be applied to a wide verity of products. In this process initially, gel coating is applied on the prepared mold surface for ease of removal of composites from the mold. After the gel curing natural fiber mats are manually placed inside the mold and thin coat of the resin is applied on the mats manually. Hand roller is used to distribute the resin equally over the mat by wetting the reinforcing fiber completely and also to remove the entrapped air. This procedure will be carried out until it reaches the required thickness.

A similar method is also used to develop the particulate composites in which reinforcing long fibers chopped into short fibers and mixed with natural or synthetic resin then which will be poured into prepared size and shape of the mold. After the sufficient amount of time is given for curing composite is removed from the mold for further processing. The main limitation with this process is delamination of fibers if the resin is not applied properly and time consumption for curing.

Compression Molding Technique

Compression molding (Wambua *et al.*, 2003; Kumar *et al.*, 2011; Bakare *et al.*, 2010; Dayo *et al.*, 2017) is a high volume and high-pressure technique used to fabricate the high strength composite materials. This method has the ability to produce large and complex shapes and it is economical compared resin transfer molding and injection molding. In this process, the composite can be produced with unidirectional mats, bi-directional fabrics, randomly oriented composites or chopped strands. Application of heat and pressure is used in this method. Fig. 6 shows the schematic of the compression molding technique. In which charge (stacking laminates or chopped fibers with resin) is placed inside the mold cavity which of the required shape of the component. The upper part of the mold is closed and pressure is applied to force the premixed charge to take shape of the mold cavity.

Table 5 Literatures on natural fiber reinforced biodegradable composites

References	Reinforcement	Matrix	Processing Method	Properties	Major findings
Wambua et al. (2003)	(a) Sisal: 40% (b) Kenaf: 30%, 40%, 50% (c) Hemp: 40% (d) Jute: 40% (e) Coir: 40%	Polypropylene	Compression molding using a film stacking method at 180°C for 2 min at 5 bar pressure	● Tensile strength ● Flexural strength ● Impact strength	● Coir composites showed the lowest mechanical properties and hemp composites showed the highest mechanical properties. ● Coir composites displayed higher impact strength than jute and kenaf composites.
Fung et al. (2003)	Sisal fiber yarns: 10%	Polypropylene	Injection molding with two temperature profile: Low temperature (LT): High temperature (HT)	● Thermal gravimetric analysis (TGA) ● Tensile strength	● Incorporation of 10 wt% of sisal fibers increases Young's modulus by about 150%, and the tensile strength of about 10%. ● The reinforcement efficiency for LT specimens is slightly higher than the HT samples.
Anuar and Zuraidda (2011)	Kenaf fiber: 20%	1. Thermoplastic natural rubber 2. Polypropylene/ethylene–propylene–diene–monomer	Double melt blending method using Haake internal mixer	● Tensile strength ● Flexural strength ● Impact strength	● Kenaf fiber has greatly enhanced the impact strength for both types of composite.
Harish et al. (2009)	Coir fiber	Epoxy – CY205	Hand lay-up technique	● Tensile strength ● Flexural strength ● Impact strength ● Fractography	● Coir/epoxy composites exhibit the tensile strength 17.86 MPa, flexural strength 31.08 MPa and impact strength of 11.49 kJ/m².
Kumar et al. (2011)	(a) Sansevieria cylindrica, (b) Waste silk, (c) Jute, (d) Drumstick	Polyester resin	Hand lay-up technique with compression molding	● Tensile strength ● Flexural strength ● Dielectric properties	● Tensile and flexural properties increase with fiber volume fraction. ● The dielectric strength of Sansevieria cylindrica fiber composites increase with an increase in volume fraction of fiber and which is not observed in many of the natural fiber composites.

(Continued)

Table 5 Continued

References	Reinforcement	Matrix	Processing Method	Properties	Major findings
Junior <i>et al.</i> (2010)	Coir fiber	Polyester resin	Hand lay-up technique (Molding and pouring)	● Tensile strength ● Fractography	● Continuous coir fibers incorporated into polyester matrix composites do not improve the tensile strength and the stiffness. ● The weak interface between the coir fiber and the polyester matrix, which allows cracks to be nucleated and propagate along the fibers/matrix interface.
Bakare <i>et al.</i> (2010)	Sisal fiber: 10%, 20%, 25% and 30%	Rubber seed oil-based polyurethane	Closed mold method	● Spectroscopy analysis ● Fourier Transform Infrared (FTIR) spectroscopy analysis ● Thermal Gravimetric Analysis (TGA) ● Water absorption behavior	● The strength of the composites increases with fiber loading. ● The tensile and flexural strength and a flexural modulus of the bio-composites vary between 57 and 119 MPa, 69–103 MPa and 2.28–3.25 GPa, respectively which are greater than un-reinforced rubber seed oil-based polyurethane. ● The loss in tensile strength is observed at 25% and 30% fiber loading after composite immersed in water for 30 days.
Ashok Kumar <i>et al.</i> (2010)	Sisal fiber and glass fiber hybrid	Epoxy resin	Hand lay-up followed by post-curing at 70°C for 1 h	● Hardness ● Impact strength ● Frictional coefficient ● Chemical resistance	● The fiber length of 2 cm hybrid composites exhibits better properties compared to 1 cm and 3 cm fiber length.
Ramesh <i>et al.</i> (2010)	Black Cotton soil with Coir fiber - 0.5%–3% (by weight of soil) with aspect ratio of 20, 40, 60, 80, 100 and 120 + Lime	–	Simple compacting process	● Compaction test ● Moisture absorption ● Compression strength	● Addition of randomly distributed coir fiber in black cotton soil increases strain and sample shows ductile properties. ● Addition of lime to black cotton soil increases the strength but samples show brittle properties.
Yuanjian and Isaac (2007)	Hemp fiber mat	Polyester resin	Hand lay-up method and curing with the application of low pressure (40 kPa) and high pressure (2 MPa)	● Tensile strength ● Low-velocity impact strength ● Fatigue test	● Composite of non-woven hemp fiber mat reinforced polyester cured at low pressure shown poor mechanical properties. ● In order to achieve better mechanical properties composites should be cured at high pressure to accommodate high fiber fraction.
Oksman <i>et al.</i> (2009)	(a) Sisal (b) Banana (c) Jute (d) Enzyme retted flax fibers (Fiber fraction: 20 wt%–45 wt%)	Polypropylene (PP)	Long fiberthermoplastics (LFT) processing method – LFT extrusion	● Flexural strength ● Izod and Charpy test ● Morphological study	● When adhesion between the reinforcement fibers and matrix is poor, the high fiber l/d ratio, high microfibrillar angle, high fiber properties, have limited impact on the mechanical performance of the composites.
Lee <i>et al.</i> (2009b)	(a) Kenaf (b) Jute (Fiber fraction: 10%, 20%, 30%, 40%, 50%, and 70 wt%)	Polypropylene (PP)	Carding process	● Tensile strength ● Flexural strength ● Fiber Volume Fraction, ● Void Content and Surface Morphology	● Kenaf fiber reinforced polypropylene composites have an optimum nominal fiber fraction of 30% ● Jute fiber reinforced composites have an optimum fiber fraction of 40% by weight at which the tensile and flexural modulus are the highest, while the reduction in strength is minimal.

Table 5 Continued

References	Reinforcement	Matrix	Processing Method	Properties	Major findings
Bledzki <i>et al.</i> (2007)	(a) Abaca fibers (b) Jute fibers (c) Flax fibers	Polypropylene (PP)	Mixer-injection molding	● Tensile strength ● Flexural strength ● Charpy test (Impact) ● Odour measurement ● Morphology	● Composite with 40% abaca fiber loading shown better mechanical properties. ● Abaca-PP composites shown better damping characteristics. ● Jute-PP and flax-PP composites discharged less odorous gas than abaca-PP composites.
Lee <i>et al.</i> (2009a)	Kenaf fiber: Weight fractions 10%, 30%, 50%, 70%	Poly lactic acid (PLA)	Carding process	● Flexural strength ● Dimensional stability and water absorption ● Dynamic mechanical analysis (DMA) ● Differential scanning calorimetry (DSC) ● Thermogravimetric analysis (TGA)	● Formulation of 50% kenaf and 50% PLA fibers represents an optimal formulation which may prove useful in a variety of applications. ● These materials can be successfully utilized to manufacture automotive headliners.
Angelov <i>et al.</i> (2007)	Flax fibers	Polypropylene (PP)	Pultrusion	● Flexural strength ● Impact strength	● The composites developed by pultrusion process exhibit satisfactory mechanical performance, similar to those of the composite manufactured by compression molding.
El-Tayeb (2008)	Sugarcane fibers	Unsaturated polyester	Hand-lay-up and open mold techniques	● Tribological properties	● Sugarcane fiber reinforced polyester ● SCRPP composite offers a good degree of wear resistance and friction coefficient comparable to glass fiber reinforced polyester GRP when sliding against stainless steel. ● Wear rate decreases with increasing the fiber length from 1 to 5 mm and then increased at 10 mm fiber length, indicating that there exists a critical fiber length (close to 5 mm) at which the wear rate was a minimum.
Chin and Yousif (2009)	Kenaf fibers	Epoxy resin	Direct mixing and pouring in a mold with application of Vacuum	● Pull-out test ● Tribological properties	● Fiber orientation had a pronounce influence on the frictional and wear performance of the composite.
Azwa and Yousif (2013)	Kenaf fibers	Epoxy resin	Direct mixing and pouring in a mold with application of Vacuum	● Thermogravimetric analysis	● Addition of fibers into the epoxy composites improves the thermal stability of the composites. ● Kenaf fiber/epoxy composites will suffer a great reduction of its mechanical properties at 150°C temperature.
Arib <i>et al.</i> (2006)	Pineapple leaf fiber	Polypropylene (PP)	Carver press a machine with a temperature and pressure control	● Tensile strength ● Flexural strength	● Tensile and flexural properties increased as the fiber volume fraction increased ● Flexural properties are lower compared to previous work may be due to lower values of flexural properties may be attributed to fiber to-fiber interaction, voids and dispersion problems.

(Continued)

Table 5 Continued

References	Reinforcement	Matrix	Processing Method	Properties	Major findings
Arrakhiz <i>et al.</i> (2012)	Coir fiber treated with Alkali, Ether, Silane	High-density polyethylene (HDPE)	Compounding and casting	● Chemical analysis ● Tensile properties ● Torsion properties	● Chemical treated coir fiber composites shown better mechanical properties compared to untreated.
Alavudeen <i>et al.</i> (2015)	Banana/kenaf fiber hybrid	Unsaturated polyester	Hand lay-up technique followed by post-cured in an oven at 50°C for an hour	● Tensile strength ● Flexural strength ● Impact strength ● Fractography	● Tensile, flexural and impact strengths of the woven hybrid composite of banana/kenaf fibers are superior to those of the individual fibers. ● Fractography studies indicate better fiber-matrix adhesion exists in the hybrid composite due to the interlocking of fibers.
Boopalan <i>et al.</i> (2013)	Jute and Banana fiber hybrid	Epoxy resin	Hand-lay-up technique followed by a light compression molding technique	● Tensile strength ● Flexural strength ● Impact strength ● Thermogravimetric analysis (TGA) and heat deflection temperature analysis (HDT).	● Mechanical properties such as tensile strength, flexural strength and impact strength are found to be maximum for 50/50 weight ratio of jute and banana fiber reinforced epoxy hybrid composites ● Moisture absorption study of hybrid composite shows the minimum moisture uptake is by 50:50 hybrid composites.
Codispoti <i>et al.</i> (2015)	(a) Jute fibers (b) Flax fibers (c) Sisal fibers (d) Hemp fibers	Epoxy resin, Polyester	Wet lay-up technique and vacuum infusion process	● Tensile properties	● Wet lay-up is, most probably, the easier and faster. ● Flax fibers are the most suitable natural fibers to manufacture composite materials for strengthening existing structures, both in terms of strength and stiffness.
Gunti <i>et al.</i> (2018)	(a) Jute fibers (b) Sisal fibers (c) Elephant gras	Poly lactic acid (PLA)	Vertical injection molding technique	● Tensile strength ● Flexural strength ● Impact strength ● Water absorption study ● Thermal degradation study	● Mechanical properties increased initially after 20% fiber loading properties decreased. ● Water absorption for all composites increased gently during the first 24 h and then leveled-off. ● Degradation was high at untreated fiber composites.
Anand <i>et al.</i> (2018)	(a) Jute fiber (b) Kenaf fiber (c) Jute/Kenaf hybrid	Epoxy resi	Hand-lay-up technique	● Tensile strength ● Compressive strength ● Flexural strength ● Impact strength ● Moisture absorption study ● Morphology study	● Mechanical properties of treated hybrid fiber reinforced epoxy composites show excellent figures than other conventional fiber reinforced polymeric materials. ● Rougher surface and increased effective surface area of the chemically treated fibers facilitated better interaction between the fiber and matrix.
Chaudhary <i>et al.</i> (2018a)	(a) Jute fiber (b) Hemp fiber (c) Flax fiber (d) Jute/Hemp/ Flax/ hybrid	Epoxy resin	Hand-lay-up technique	● Hardness ● Tensile strength ● Flexural strength ● Impact strength ● Morphology study	● Hybrid composites such as Jute/Hemp/ Flax/Epoxy shown better properties due to the combined properties of four materials and improved bonding.

With application of force and heating the charge it is allowed to cure for some time and after cooling using ejector pin final component is removed from the mold cavity. Extra material is trimmed from the final component to achieve the final shape. This method can be used to produce precision components with a large scale. When it is used to produce natural composite operating temperature should be maintained based on the decomposition temperature of fibers used to produce the components.

Vacuum Assisted Resin Transfer Molding Technique

It is low pressure and low-temperature technique in which liquid thermo-set resin is transferred inside the mold consists of fiber mats. **Fig. 7** shows the vacuum assisted resin transfer molding technique (Sanjay *et al.*, 2018). This method is gained popularity because of the capability of manufacturing a high-performance structure with a large scale. In this process, a vacuum bag is used to apply pressure on the mats and to distribute the resin uniformly.

Natural fiber mats are placed inside the mold and peel ply is placed on the stacked fiber mats. Two tubes are connected to the mold at the two ends to pump and to transfer the liquid resin inside the mold through the fibers using the pump. The extra resin is removed at the other end of the mold. The components are removed from the mold after it allowed for sufficient time for curing. In this process, the resin can be transferred directly from the top of the reinforced stacks or from the side based on the size and shape of the component.

Injection Molding Technique

Researchers and industries are successful in using injection molding (Fung *et al.*, 2003; Lee *et al.*, 2009a,b) technique shown in **Fig. 8** to manufacture the natural fiber composites. In this process raw materials are in the form of pellets, granules or powder is fed inside the barrel from the hopper. Further, it is conveyed along the barrel where it is heated with the application of heaters placed in the barrels and sheared with the application of movement of the screw. The pellets fed from hopper remains dry throughout the process and resin melts and mixes with the fiber pellets. The molten composite is further compacted and injected to the mold cavity through the nozzle with the application of the screw movement.

This process consists (a) feed zone (b) compacting zone and (c) metering zone. Electric motor with gear arrangements is used to drive the screw and based on the requirement single screw and multi screws are used to achieve the better compacting. After curing, the components are removed from the mold for further processing. The main advantage of this method is, near to net shape can be achieved with good surface finish and dimensional accuracy. Limitations are high capital investment and more time

is required to design and develop the molds. The major challenge in this process is: maintaining the barrel temperature which is equivalent to the decomposition temperature of the natural fibers.

Pultrusion Technique

The pultrusion technique (Angelov *et al.*, 2007; Sanjay *et al.*, 2018) is a method reported in the literature, which is feasible to use for manufacturing the natural fiber composites as shown in Fig. 9. It is a continuous manufacturing process used to manufacture a fixed type of profiles based on the required shape of the composite with any length. In this process a continuous fiber from the roving is pulled and processed through the resin bath where the melted resin is infused with the fibers and shaped to the required profile. Further, it is cooled to the normal temperature at the cooling chamber and cut using cut off saw to the required length. This process is also used to manufacture the pellets which are used in the injection molding process. A major challenge associated with this process is controlling the viscosity of the resin bath which helps in wetting of fibers easily and also controlling the temperature to prevent the fibers from thermal degradation.

ASTM Standards for Testing

Literature shows there have been numerous characterization techniques are used to evaluate the properties such as tensile, compression, flexural, shear, fracture toughness, fatigue, impact, physical and chemical properties of the natural fiber reinforced polymer and laminated composites. The varying degrees of standardization methods are used in industries as well as by

researchers based on the requirements. Some of the standards used to evaluate the basic properties of the composites are listed in Table 6 and most of the standards are selected from American Society for Testing and Materials (ASTM).

Applications

Natural fiber reinforced composites currently occupied many sectors due to its superior qualities such as low density, biodegradable and recyclable, acceptable specific strength, ease of availability, reduced tool wear during the molding process, better acoustic properties, low cost and easy of processing. Fig. 10 shows the history of the application of composites includes various materials used with the time frame. The use of natural composites started 3000 years ago where clay and mud reinforced by straw fibers to build the walls in the construction of huts. The first successful use of natural fiber composites was attempted in 1939 where flax is mixed with a phenolic matrix to manufacture fuselage skins. Hemp is used to manufacturing a prototype composite car by Henry Ford in 1942. Presently it is occupied many sectors by replacing synthetic fiber composites mainly to reduce the cost and to overcome disposal problem associated with other materials (Sanjay *et al.*, 2018).

Applications	Clay/mud reinforced composites	Fuselage skins of spitfires	Prototype composite car by Henry Ford	Body of trabant car in Germany	Number of automotive applications	E&E: Cases of cellular phones	Sporting goods	Roof top wind turbine blades
Materials								
Time Frame	In Egypt clay/mud reinforced by straw to build walls	Shortage of aluminium in England, led to use natural fiber		First production car built from natural fiber composites				
	3000 year ago	1939	1942	1950-1990	2000 onwards	2004 onwards	2006 onwards	2014

Automotive and construction industries are using natural fiber composites in large scale (Mohanty *et al.*, 2005). This section highlights some of the important applications of the natural fiber composites in

- (a) Automotive industry
- (b) Construction industry
- (c) Sports industry
- (d) Miscellaneous Products

Automotive Industry

Ever since the major transition took place in the development of new lightweight and economical biodegradable composite materials automotive sectors are the major consumers. Natural fiber reinforced composites are commonly used in door panels, seat back, interior decoration, body panel etc. (Fung *et al.*, 2003; Mohanty *et al.*, 2005; Cheung *et al.*, 2009; Sanjay *et al.*, 2018; Zaidi *et al.*, 2018). Table 7 shows some of the natural fiber composites used in automotive industries.

Construction Industry

The construction industry constitutes the second largest sector to employ natural materials in a wide range of products. Wood flour, flax, rice husk and bagasse fibers are extensively used in light structural walls, insulation materials, floor and wall coverings, window frames, geotextiles and thatch roofing. The key drives for using natural fibers in construction industry are low life-cycle cost, low and easy maintenance, eco-friendly, easily available and friendly government regulations (Mohanty *et al.*, 2005). Natural fibers are also used as reinforcements with cement for building materials.

Sports Industry

Sports industries also major consumers of natural fibers. Some of the recent developments in manufacturing sports equipment using natural fiber composites are: flax fibers are used to manufacture tennis racket, bicycle frames, fork and seat post in medium size due to its superior anti-vibration characteristics. Hemp fibers are also used in the manufacturing of snowboarding. Carrot fibers are used to manufacture fishing rods (Suddell, 2008).

Miscellaneous Products

Manufacturing industries applications such as grinding wheel discs with 1 million units being produced each year under the trade name Plantex, in this instance hemp and polypropylene (PP) are being used to create the backing plates for these industrial products. Cosmetic packaging is an area also seeing the adoption of natural fibers. In the USA, a lipstick casing made from Flax fibers and PP which has been on sale for 4 years selling 4 million units per year. Funeral Urns made from natural fibers and PLA which after a limited time will naturally decompose leaving no physical residue behind. Key events such as the 2008 Olympics

Table 7 Natural fiber composites applications in the automotive industry

<i>Manufacturer</i>	<i>Model</i>	<i>Application</i>
Audi	A2, A3, A4, A4 Avant, A6, A8, Roadstar, Coupe	Boot-liner, spare tire-lining, side and back door panel, seat back, and hat rack
BMW	3, 5 and 7 series and other Pilot	Seat back, headliner panel, boot-lining, door panels, noise insulation panels, and molded foot well linings
Citroen	C5	Interior door paneling
Daimler Chrysler	A, C, E, and S class, EvoBus (exterior)	Pillar cover panel, door panels, car windshield/car dashboard, and business table
Fiat	Punto, Brava, Marea, Alfa Romeo 146, 156, 159	Door panel
Ford	Mondeo CD 162, Focus	Floor trays, door inserts, door panels, B-pillar, and boot-liner
General Motors	Cadillac De Ville, Chevrolet Trail Blazer	Seat backs, cargo area floor mat
Honda	Pilot	Cargo area
Lotus	Eco Elise (July 2008)	Body panels, spoiler, seats, and interior carpets
Mercedes Benz	C, S, E, and A classes	Door panels (flax/sisal/wood fibers with epoxy resin/UP matrix), glove box (cotton fibers/wood molded, flax/sisal), instrument panel support, insulation (cotton fiber), molding rod/apertures, seat backrest panel (cotton fiber), trunk panel (cotton with PP/PET fibers), and seat surface/backrest (coconut fiber/natural rubber)
	Trucks	Internal engine cover, engine insulation, sun visor, interior insulation, bumper, wheel box, and roof cover
Mitsubishi		Cargo area floor, door panels, and instrumental panel
Opel	Vectra, Astra, Zafira	Door panels, pillar cover panel, head-liner panel, and instrumental panel
Peugeot	406	Front and rear door panels, seat backs, and parcel shelf
Renault	Clio, Twingo	Rear parcel shelf
Rover	2000 and others	Rear storage shelf/panel, and insulations
Saab	9S	Door panels
Seat	—	Door panels, Seat backs
Saturn	L300	Package trays and door panel
Toyota	ES3	Pillar garnish and other interior parts
Toyota	Raum, Brevis, Harrier, Celsior,	Floor mats, spare tire cover, door panels, and seat backs
VAUXHALL	Corsa, Astra, Vectra, Zafira	Headliner panel, interior door panels, pillar cover panel, and instrument panel

hosted by China and held in Beijing (predominantly) presented an ideal opportunity to utilize natural materials on a global stage. This event alone used 80,000 tonnes of natural fibers, mainly in the construction of buildings (Suddell, 2008).

Advantages and Limitations

Some of the advantages of natural fiber composites are (Anandjiwala and Blouw, 2007; Pandey *et al.*, 2015):

- Low specific weight, which results in higher specific strength and stiffness than glass. This is a benefit especially in parts designed for bending stiffness.
- It is a renewable resource and the production requires little energy.
- Producibile with low investment at a low cost, which makes the material an interesting product for low-wage countries.
- Friendly processing, no wear of tooling, no skin irritation.
- Thermal recycling is possible, where glass causes problems in combustion furnaces.
- Good acoustic insulating properties.

Some of the limitations of natural fibers are (Anandjiwala and Blouw, 2007; Pandey *et al.*, 2015):

- Lower impact strength.
- No control over property, depending on unpredictable influences such as weather.
- Moisture absorption, which causes swelling of the fibers.
- Restricted maximum processing temperature.

- Lower durability, fiber treatments can improve this considerably.
- Lower thermal resistance.
- Price can fluctuate based on harvest results or agricultural politics.

Research Challenges

In spite of the wide range of applications of natural fiber reinforced composites in automotive, constructions, sports and some of the miscellaneous products these composites still exhibits significant challenges in full-scale utilization and their advancement. Some of the major challenges are low mechanical properties, poor moisture resistance, low fire resistance, variability in the quality of the fibers and difficulties in manufacturing. Another major issue associated with the development of natural fiber reinforced composites is adhesion between fiber and matrix which has a great impact on delamination. The manufacturer should have a good knowledge of properties of fiber such as wetting, adhesion properties and weight fraction of fiber-matrix materials to avoid delamination issues. Machining of these composites also challenging because fiber pullouts and delaminations are the common problems observed by researchers during the machining. These materials also pose challenges to material scientists particularly with the acceptance criteria for being their performance and cost, despite the renewability and recyclability of the matrix and the reinforcements used (Satyanarayana *et al.*, 2009).

Conclusions

Natural fiber reinforced composites offers several advantages such as biodegradability, eco-friendly, abundant, renewable, low-density and many more. These are potential materials to replace the synthetic fiber reinforced composites. This article presents major findings reported in the literature on the study conducted on a different aspect of natural fiber reinforced composites. Standards used for testing materials, manufacturing techniques available and potential use of natural fiber reinforced composites in a different field are described in this article. Some of the major conclusions drawn from this study are:

- Natural fiber reinforced composites are the best solution to meet the growing interest in reducing the environmental impact of synthetic fiber reinforced composites.
- Natural fibers are classified based on the source from where fibers are extracted and grouped under plant fibers, animal fiber and mineral fibers.
- Some of the commonly used manufacturing techniques of natural fiber reinforced composites are hand layup technique, a compression molding technique, vacuum-assisted resin transfer molding technique, injection molding technique and pultrusion technique.
- Major factors to be considered during the manufacturing of natural fiber reinforced composites are fiber/matrix selection, composition, fiber size, shape, fiber treatments and post-curing.
- Hybridization of multiple natural fibers reinforced with matrix has been recognized as the best possible solution to meet the different category of the customers.

Polymer Blends and Composites From Renewable Resources

Mohd H Othman, Tun Hussein Onn University of Malaysia, Johor, Malaysia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Research about renewable polymers have been carried out for centuries. However, the interest of utilizing this material through various types of blend and composites had become increasingly thriving since the limitation of crude oil and more concern about the greener material that is environmentally friendly. With more technology in microstructure elucidation, it is possible to apprehend more knowledge regarding the relationship of properties and structure. Nevertheless, more efforts are needed to achieve better properties of the renewable polymer blend and composites, and at the same time troubleshooting the shortcomings of this new material. In order to do that, basic understanding was needed with regard to the types of renewable materials, the structures, the properties and the potential application. There are three types of renewable polymers that have been used as the matrix, which are natural polymers, synthetic polymer (natural monomers) and fermentation of microbial's polymers (Yu *et al.*, 2006). Hence, the manufacturing route for bio polymer also follows these three categories. The bio-based polymer manufacturing route is displayed as Fig. 1 (Okan *et al.*, 2019). In this article, more explanation shall be made based on these three categories of renewable polymer matrix.

Blends and composites obtained from renewable resources usually quoted as green composites. Typically green composites were friendly to the environment and becoming an alternative to polymers made from petroleum and traditional composites. To reduce the fossil oil depletion, renewable resources like vegetable oils, carbohydrates and proteins have been utilized as biopolymer matrices. Hence, this biocomposites have increased the possibility for sustainable and 'biodegradable', and meet the criteria of 'green materials' (Jadhav *et al.*, 2019). Currently, green material, environmentally friendly material, sustainable material and eco-efficiency, are some of the terms that directing the advancement of the succeeding group of new materials, products, and processes. Materials made from renewable resources (agricultural/biomass) such as biocompatible/biodegradable polymers could dominate the future by replacing the petroleum feedstock. Besides utilizing renewable resources as the matrix, it can be also exploited as the fiber reinforcement to strengthen the matrix. For instance, natural/bio fiber reinforcement is developing as a feasible alternative to reinforcement made from glass fiber. It can be applied in automotive industries, domestic utilities and several building structures. Such natural/biofibers line bamboo, sisal, banana/pineapple leaves, kenaf, hemp, flax and jute, with various types of matrix made from polymer matrices, either renewable or not, have been studied extensively by many researchers (Mohanty *et al.*, 2002).

Bio-based polymers not only replace existing polymers in a number of applications, nonetheless also provide new combinations of properties for new applications. For bio-based polymers like PLA and PHA, additives are being developed to improve their performance, by blending with other polymers or making new copolymers (Shivam, 2016). Many researchers are attempting to create different products by utilizing natural fibers as reinforcing agents. Hence, it is important to draw out the issues related to

Fig. 1 Bio-based polymer manufacturing route. Credit to: Okan, M., Aydin, H.M., Barsbay, M., 2019. Current approaches to waste polymer utilization and minimization: A review. *Journal of Chemical Technology & Biotechnology* 94 (1), 8–21.

the processing of natural fibers and their green composite has been tended to. The types of fibers utilized as a part of composites, surface modifications and processing techniques of these green composites were some of the important issues that need to be studied among researchers. Based on previous findings, it is presumed that the natural fibers are the potential replacement option for unadulterated manufactured fibers and the utilizations of these fiber composites will increase in the future (Ramesh and Deepa, 2019). Henceforth, the compilation of previous research related to this topic will be the essence of this article for future reference and guidelines.

Natural Polymer

The first type of renewable polymer which is going to be discussed is natural polymer. This material, mostly are hydrophilic, due to the existence of either hydroxyl or polar groups. Differently, most of synthetic polymer is sensitive to moisture (hydrophobic). Therefore, combining these two materials will be fascinating, whereby a wide range of biodegradable material could be obtained, since modern technology could utilize the knowledge of compatibilizer usage and reactive extrusion could improve the adhesion of this combination (Yu *et al.*, 2006).

There are many extensive kinds of renewable resources' derived of polymer that could be used in many different ways. The usage of some of these materials are not being optimized. It can be grouped into several classes according to their chemical properties or physical structure. Fig. 2 shows the classification of natural polymers (Kaplan, 1998; Gross and Scholz, 2001).

Based on the natural polymer native setting, it can develop certain functions that can be utilized for engineering applications. Generally, natural polymer was used as adhesives, coatings, gels, foams and films. To quote one example, the protein could become a catalyst and a structural material. Polysaccharides can be functional as wastewater adsorbents, energy utilization and drug loaded particles. As for lipid, it can be used as energy stores, structure of cell membranes, signaling and cosmetics. Another example is starch that had been applied in corrugated board adhesives, papermaking and textiles. However, there are certain drawbacks of this material. The disadvantages of this material typically related to their dominant hydrophilic character, such as rapid degradation rate with weaker mechanical properties at watery condition (Kaplan, 1998).

To overcome this problem, the idea of blending the natural polymer with synthetic polymer had come across the researchers. The technology of blending and extrusion could assist this process, whereby most of the aim is to combine two or more materials with cautions not to alter the properties radically, nonetheless obtaining several better properties and provide the solution of the drawbacks (Kaplan, 1998). However the job is not that easy. Failures could happen when the outcomes were not satisfying. For instance, back in the 1970s and 1980s, several types of polyolefin have been blended with starch to evaluate their performances. Unfortunately, the produced blend was not environmentally friendly since it cannot be decomposed through natural resources. Hence it could contaminate the land by polluting the earth. Herein, the gain of using natural polymer was absent (Yu *et al.*, 2006). However, there are more successful findings about the blend of natural polymers. Several examples like chitosan, elastin, natural fibroin, silk, chitin and keratin have been deliberate as a component of blends and composite from renewable resources. Table 1 shows the blending of natural polymers with their applications or advantages (Sionkowska, 2011).

The potential application that could be obtained from the blend of natural polymer and synthetic polymer was heavily depended on the processing factors. For instance, the age of the tissue will influence the solubility of collagen (Miyahara *et al.*, 1982). As for collagen, it could be blended with synthetic polymer in a solvent. It could be applied in biomedical field as films and sponges. A good quality of hydrogels also could be produced by blending the collagen with other hydrophilic polymers (Wang *et al.*, 2011). A research about the blend of collagen–chitosan hydrogel for endothelial differentiation and angiogenesis had

Fig. 2 Classification of natural polymers. Credit to: Kaplan, D.L., 1998. Biopolymers From Renewable Resources: Macromolecular Systems-materials Approach. Springer-Verlag Berlin Heidelberg. Gross, R.A., Scholz, C., 2001. Biopolymers From Polysaccharides and Agropoteins. American Chemical Society.

Table 1 Blends of natural polymers and their applications/advantages

Blends	Application/Advantages
Chitosan/poly (vinyl alcohol)/poly (ethylene oxide) and poly (vinyl pyrrolidone)	Oral gingival delivery systems
Chitosan/poly(vinyl alcohol)	Superior in other properties compared to chitosan, Used in drug delivery systems
Chitosan/poly (vinyl pyrrolidone)	Sterilization, drug release system and release profile of a drug
Elastin hydrolysates and collagen	Increase of biocompatibility, elasticity, less sensitive to ultraviolet irradiation
Natural fibroin/synthetic polymers	Scaffolding, cost reduction, mimicking the structure and/or function of the native extracellular matrix, biosensors
Silk fibroin/Nylon-6	Thermal stability
Silk fibroin/wool keratose	Nanofiber preparation, heavy metal ion adsorbent
Silk/polyurethane	Elastic biofibers, smooth surface, dense structure, and considerably higher strength
Chitin/silk fibroin	Biomimetic nanostructured scaffolds
Chitosan/silk fibroin/methoxy poly(ethylene glycol)- <i>b</i> -poly(DL-lactide)	Film strength increment and a decrease in film flexibility and wettability
Keratin/chitosan	Adjustment of mechanical properties. Strong, flexible film. Supported fibroblast attachment and proliferation

Note: Sionkowska, A., 2011. Current research on the blends of natural and synthetic polymers as new biomaterials. *Progress in Polymer Science* 36 (9), 1254–1276.

proven it can be used as biodegradable polymeric scaffolds (Deng *et al.*, 2010). Furthermore, the findings of electro spun collagen–chitosan– thermoplastic polyurethane nano fibrous scaffolds could be widely used in medical applications (Huang *et al.*, 2011).

The most important notes that need to be monitored closely was the solubility of the polymeric components in a common solvent. One of the common solvent that had been used was water, because most of the natural polymer could be solvable in water. Not only act as a solvent, the water could also become a dispersion medium and plasticizer if the preparation of numerous natural polymer blends and composites (Matveev *et al.*, 2000). For example, proteins and polysaccharides structure–property relationships was developed based on their interaction with water and with each other in a water medium. In order to illustrate the role of water in these materials, researchers should carry out certain analysis of the glass transition temperature and thermal profile (Yu *et al.*, 2006).

To quote one example, in term of the application of natural polymers blends and composite, some researchers have established the findings in utilizing this material for drug delivery devices. The drug delivery process has been embedded in the research about experimental design optimization and biodegradation behavior of poly (vinyl alcohol)-collagen hydrolysates (Alexy *et al.*, 2003) and microcapsules formed by polyelectrolyte copolymer and modified collagen have been successfully performed (Quek *et al.*, 2004). These drugs were released by diffusion through the polymer barrier, by erosion of the polymer material, or as a result of the combination of both. According to the results, the delivery system design obtained from the exploitation of this renewable polymers was flexible enough as compared with the non-biodegradable polymeric matrices. In this system, which have been predetermined rate and duration, it was found that the bioactive substances were released as they degrade to the desired area with an effective dose (Sionkowska, 2011).

Synthetic Polymers

Monomers from natural resources could be used to produce synthetic polymers. This progress had provided potential upgrades to produce polymers from renewable resources. One of the famous examples of this material was poly (lactic acid). Another name of this material is polylactide. This thermoplastic aliphatic polyester is biodegradable and bioactive. Poly(lactic acid) is made from renewable resources, which is agricultural products such as sugarcane, chips, cassava roots, and corn starch. Through the fermentation of these agricultural resources, the controlled depolymerization of lactic acid could produce the lactide in a cyclic dimer. This technology was not new, but the blends of this material with other material have lots of potential. Not only it can be used as biodegradable material, poly (lactic acid) also has very low or no toxicity and high mechanical performance, as compare with other domestic polymers (Yu *et al.*, 2006).

Conversely, the disadvantage of this material is the thermal stability. It is generally not sufficiently high enough for poly (lactic acid) to substitute certain commercial polymer applications. Hence, more investigations have been executed towards many types of poly (lactic acid) blends and composites, in order to overcome the thermal stability (Yu *et al.*, 2006). For instance, a review had been made about several researches towards the stereocomplex formation, which was made from enantiomeric poly (lactic acid)-PLA, poly (L-lactic acid)-PLLA and poly (D-lactide)-PDLA. The blend of these materials was proposed because of the strong interaction between PLLA and PDLA chains. It was found that the PLLA/PDLA blend has a higher hydrolysis resistance, as compared with pure PLLA and PDLA, even when it was amorphously made. The X-ray diffractometry and differential scanning calorimetry results also elucidated that all initially amorphous poly (lactic acid) films remained amorphous, even after autocatalytic hydrolysis for 16 months for PDLA film and 24 months for PLLA/PDLA non-blended films

and PLLA/PDLA (1/1) blended film. Correspondingly, after the hydrolysis process was completed in 24 months, the detected melting peaks were attributed to those of homo and stereocomplex crystallites. However, this condition was not happening through the autocatalytic hydrolysis. Therefore, based on the results, the enhancement of thermal stability for PLLA/PDLA blend could be achieved through melt enantiomeric polymer blending, and this condition is better than pristine PLLA and PDLA. Further research also have been carried out toward film of PLLA and PDLA and their equimolar enantiomeric blend (PLLA/PDLA). The analysis of the effects of enantiomeric polymer blending (isothermally and non-isothermally under nitrogen gas) towards the thermal stability and degradation of the prepared films. The investigation was carried out by using thermogravimetric, and the results show that the blend had augmented the thermal stability of the PLLA/PDLA films (Yu *et al.*, 2006).

It is important to control the PLA hydrolytic degradability. Hence, more researches have been conducted to clarify the effects of various components in the PLA blend systems. For instance, a research had been performed to accelerate the degradation of PLA by using poly (aspartic acid-*co*-lactide) or PAL. According to the findings, as the amphiphilic copolymer, which was attained from aspartic acid and lactide, PAL had provided several benefits through the blend with PLA, which are (Shinoda *et al.*, 2003):

- (1) PAL could form a homogeneous mixture when added together with PLA.
- (2) The films made from PAL/PLA is homogeneous without weakening the characteristic of PLA.
- (3) The PLA transparency shall be remained.
- (4) The blend can performed as antistatic agents by adding with poly (sodium aspartate-colactide).
- (5) The degradation rate of PLA in water, soil and compost can be boosted.
- (6) Hydrolysis resistant.
- (7) Long shelf life.
- (8) As for the usage of polybutylene succinate and polycaprolactone, it could raise the rate of the non-enzymatic as the additive component.
- (9) Enhanced the PLA's thermal stability.

Besides that, this research also clarified the usage of poly DL-lactic acid (PDLLA) could accelerate the degradation of the blend, because of its amorphous structure. Consequently, it is possible to control the degradation time of PLLA/PDLLA blends, by applying different blending ratios of PLLA and PDLLA (Shinoda *et al.*, 2003).

The extension of this research have been made to find out more details about the preparation and characterization of biodegradable PLA polymeric blends. For instance, a group of researchers has prepared several blends of biodegradable PLLA and PDLLA. These blends were made by dipping the blend into dichloromethane solution with different ratios. The additional component was added to these blends, which are copolymer of ethylene oxide and propylene oxide as the surfactant. Based on the findings, the differential scanning calorimetry (DSC) shows that PLLA/PDLLA blends had two T_g values for the blend without the surfactant, but when the surfactant was added, a linear shift of the single T_g as a function of composition was appeared. It was noted also that the blend with lower percentages of PLLA had creating lower glass transition temperatures. This shows that better miscibility had been attained. As for the second analysis, the dynamical mechanical analysis (DMA) findings showed a high elastic modulus and elongation for 40/60 PLLA/PDLLA blends without the surfactant, and by adding 2% surfactant. As for another formulation with 50/50 PLLA/PDLLA, the addition of 2% surfactant into the blend had resulting the highest elastic modulus, yield strength and break strength. At the end of the research, the addition of PDLLA and surfactant towards PLLA via solution blending could bring much benefit in term of toughness and biocompatible for medical use, such as in dental and orthopedic (Chen *et al.*, 2003). Similar outcome also have been achieved, in term of the crystallinity, the glass transition behavior, the tensile modulus and the biodegradability of the blends of polylactides with high and low L-isomeric ratios of the lactate units (Urayama *et al.*, 2002).

Polymers From Microbial Fermentation

As for the third group of renewable polymer, this material was prepared through the fermentation of microbial. For instance, poly (hydroxyalkanoate)s or normally known as PHA, had been preferred to be scrutinized among new material researchers. PHA was made from a variety of micro-organisms that are molded as naturally occurring storage polyesters. The key criteria for this material to be included in the renewable polymer was the truly biodegradable and highly biocompatible properties which were obtained from the bacterially synthesized PHA. According to a review that had been made, it can say that over 90 different types of PHA blend consisting of numerous types of monomers have been attested and the affection towards this material had been snowballing.

Several bacterial species like Actinobacillus, Azotobacter, Agrobacterium, Rhodobacter and Sphaerotilus have been under focus for their ability of converting organic waste to bacterial PHA. For industrial production of biocompatible poly (3-hydroxybutyrate) (PHB), some bacterial species like Bacillus spp., Pseudomonas spp., Aeromonas spp., Cupriavidus spp. have been extensively used for their potential to produce PHB. Since the production of bio-plastic is expensive many techniques have been adopted for large scale production. But, to obtain PHB in large amount the selection of proper strains of bacteria, capable of producing or accumulating PHB is necessary (Shivam, 2016). For examples, several types of copolymer could be obtained through biosynthesis and characterization of hydroxybutyrate(HB) with 3-hydroxyvalerate(3HV), 3-hydroxypropionate (3HP), 3-hydroxyhexanoate (3HH) and 4-hydroxybutyrate (4HB) (Yu *et al.*, 2006).

The PHB and its copolymers with 3-hydroxyvalerate (PHBV) were also have been documented specimens of PHA group, whereby these materials have promoted several gains in term of biodegradability and biocompatibility over other thermoplastics with valuable mechanical properties as well. Unfortunately, the factor of cost and performances need to be monitored closely through exploring the suitable polymer to be blended with. For instance, the miscibility, morphology, mechanical behavior and other prominent characteristics of several blends and composites of PHB and PHBV with a few polyethers, polyesters, polyvinylacrylates and polysaccharides have been investigated with a wide range of properties emerges in term of crystallinity, glass transition and melting temperatures. Another imperative key that needs to be studied more was the microstructure of the blends, which could be obtained thermodynamically and kinetically. These factors were vital in directing the mechanical and the biodegradation behaviors of the blends. What is more, certain attentions need to be focused in order to elucidate the miscibility behavior differences of the blends, such as the nature of the “driving force” of the miscibility (Avella *et al.*, 2000).

Further evaluation had been made towards PHB–PHV copolymer biodegradable composites, by incorporating two particulate bioactive ceramics, which were hydroxyapatite (HA) and tricalcium phosphate (TCP), to yield new biomaterials for possible medical applications. The origin materials could be obtained easily, and could be characterized preceding to composite manufacture. It was reported that up to 30 vol% of the bio ceramics could be acquired through the recognized method made towards HA/PHB–PHV and TCP/PHB–PHV composites. Numbers of experiments utilizing tools such as thermogravimetric analysis, scanning electron microscopy, differential scanning calorimetry and dynamic mechanical analysis have been executed. Based on the results, the intended compositions of composites had been achieved and bio ceramic particles were well distributed in the polymer. With the addition of bio ceramics, lower degradation temperature was obtained and affecting the melting temperature of PHB–PHV composites. Varies type of PHB–PHV’s crystallinity was also observed according to the existence of HA or TCP particles. The increment of the storage modulus and loss modulus was paralleled by adding more and more HA or TCP content. The high stiffness could be achieved through the highest percentage of bio ceramics. In order to induce the formation of bone-like apatite, the enhanced ability of these composites have been obtained through preliminary in vitro experiments (Chen and Wang, 2002).

As one of other research, a study had been established by utilizing the diazotrophic bacteria of Azotobacter and Rhizobium genus, to produce the composite of PHB and PHBV with different molecular weight at different conditions - in vitro and in vivo. The development of numerous medical applications, such as surgical meshes, screws and plates for bone fixation, periodontal membranes, and wound dressing were also being studied. A demonstration of implanted animal tissue upon the PHB films and medical devices also had been achieved (Bonartsev *et al.*, 2007).

There are promising trend in the modern technology which have intensively made several progress through the exceptional properties of PHB and its copolymers, such as (Holmes, 1985):

- Optical active property of PHB.
- Utilization of PHB as an intravenous or oral carbon supply, with numerous of clinical benefits over glucose drip.
- Piezoelectric properties comparable to natural bone. A composite of PHB can be used to make a bone fracture fixation plate with akin characteristic of natural bone. This composite also promotes bone healing and growth. Moreover, it is biodegradable and unnecessary to be removed since it can resolve to the body.
- Controlling drug release in medical use. It can also be used as surgical pads, wound dressings and lubricant for surgeons’ gloves in fine powder form.
- With the aid of advanced equipment it can be utilized as a vascular graft or blood vessel, composed of very fine fibers, arranged to form a water impermeable tube of suitable internal diameter.

Application and Future Recommendations

Some of the recent advances had been achieved for conductive polymer composites from renewable resources, with a number of potential applications. Various filling contents and matrix polymers have been developed to give renewable polymer composites better electrical and thermal conductivity properties (Huang *et al.*, 2019).

More application of biopolymer had been discovered, such as the development of flame retardant (FR) additives from these materials. Most of the FRs prepared are problematic due to their negative impacts on human health and the environment. Furthermore, their preparations are neither green nor sustainable since they require typical organic, synthetic processes that rely on fossil fuels. Because of this, the need to develop more sustainable and non-toxic options is vital. Many research groups have turned their attention to preparing new bio-based FR additives for synthetic polymers (Hobbs, 2019).

More application in the automotive industry had been conducted with more studies towards the usage of biomaterials. Because of their low weight, these materials improve the efficiency of the automobile in terms of lower fuel consumption. Most of the major automotive industries are successfully employing natural fiber composites for the development of different automobile parts. Hence, a study of the crashworthiness and the use of these composites for the development of the interiors and exteriors of automobiles had become the interest among researchers recently (Verma and Senal, 2019).

Another opportunity for biocomposites application is to be used as automotive interior parts. The world automotive industry of interior parts is continuously optimizes the price/quality relation to gain competitiveness in the market. Nowadays, the importance of biodegradable polymers or polymers from renewable sources and the utilization of natural vegetal fibers to reinforce the polymers are increasing. These types of polymers and composite materials associated with the life cycle analysis are

gaining popularity and making a turning point in the automotive industry. A research had been conducted about the development of a novel green composite by the use of biopolymer poly (lactic acid) and natural-based cellulosic fibers in automotive interiors. As the results suggest, the incorporation of 20% fiber improves the thermal behavior of the composite without compromising the mechanical behavior of interior door trims (Loureiro and Esteves, 2019).

Renewability, Recyclability and Sustainability

In terms of recycling, the waste management system for composite from renewable resources are still in studies. Some of the international bodies, such as ICS-UNIDO had worked an activity about environmentally degradable plastics. Standardization, availability of renewable and non-renewable resources for production of environmentally degradable plastics, integration of policies and regulations relevant to waste management, life cycle approach and eco-design of product were identified as key issues in this material promotion and large scale application (Miertus and Ren, 2002).

Polymer recycling is being considered as one of the most widely accepted remedies to the threat of growing amounts of plastic waste by both the public and scientists. In practice, recycling is associated with many difficulties, such as problems related to separation, sorting and cleaning operations, lack of fiscal subsidies, instability of selective garbage separation programs, high transport and electricity costs, etc. Some novel approaches such as application in carbon capture or the synthesis of carbon nanostructures from the plastic waste are among the new process technologies of recycling. From traditional and promising polymer waste utilization approaches, there are needs for sustainable methods to reduce impacts of plastic waste on the environment. Fig. 3 shows some promising and eco-friendly plastic management approach. The same issue faced with polymer made from renewable resources (Okan *et al.*, 2019). Hence, more studies were needed to improve the waste management of this material.

In renewability and recycling, a study of thermal ageing behavior could be beneficial. Investigation of the ageing effect on biocomposites would supplement current knowledge and may help in encouraging their use in real life applications. Based on a research, an investigation had been carried out to determine the variation in various properties of bagasse fibers reinforced PLA biocomposites during accelerated thermal ageing. The study revealed that the PLA structure had deformed in biocomposites, at lower temperatures than their glass transition temperature, when subject to prolonged duration. Therefore, the study provides a comprehensive understanding of the thermal ageing of biocomposites and its effect on various properties (Lila *et al.*, 2019). Another recent application of bio polymer is the eco-friendly membrane with highest conductivity. This application contributes good cycling properties and possesses higher value of cationic transference number when compared with other electrolyte samples. A lithium ion conducting battery constructed using the highly conducting polymer membrane sample is used to light up the red LED (Perumal *et al.*, 2019).

Another method to recycle bio polymer is by applying the composite coagulant. For example, to attain an efficient composite coagulant with less environmental risks, a novel inorganic/natural polymer composite polyaluminum ferric chloride-starch graft copolymer with acrylamide and dimethyl diallyl ammonium chloride (PAFC-Starch-g-p[AM-DMDAAC]) was prepared, and applied for textile wastewater treatment. The results showed that PAFC-Starch-g-p(AM-DMDAAC) exhibited higher and more stable dye removal efficiencies than other prepared composite coagulants. For synthetic textile wastewater treatment, these composites could reduce the chemical dosage by more than 50% compared with conventional coagulation-flocculation process. Hence, it can be concluded that PAFC-Starch-g-p(AM-DMDAAC) is an eco-friendly composite coagulant with excellent performances and broad utilization range, showing promising application prospects (Zhou *et al.*, 2019).

Conclusion

As for the summary, findings from previous research that are related to the progress of renewable resources that have been exploited in polymer blends and composites. The detail explanation has been prepared based on the three categories of renewable polymers. The prominence on potential applications could inspire more research and inquiries about this special material, since it was cheaper, ecofriendly, biodegradable, and is widely used as a substitute for existing polymer from crude oils. Henceforward, the compilation of previous research related to polymer blends and composites from renewable resources had been delivered as the outcomes of this article, with the additional prospect for future direction and references.

Polysaccharide Based Rubber Nanocomposites

Shital J Sahoo, Kalyani Prusty, and Sarat K Swain, Veer Surendra Sai University of Technology, Burla, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Rubber refers to an elastomeric compound that consist of various monomeric units which form polymer and are heat cured. Rubber correctly refers to the natural gum produced from the sap of the Hevea tree (Visakh *et al.*, 2012). Usually they found in the form of colloidal emulsion in a milky white fluid which is called latex. The Hevea tree originated from Brazil which was introduced to Sri Lanka, Malaysia, Singapore and some surrounding countries where soil suited for its growth (Junian *et al.*, 2015).

Natural rubber (NR) is considered as one of the principal elastomeric unit which is widely utilized in different industries (Abdelmouleh *et al.*, 2007). In this present period, *Hevea Brasiliensis* is the only natural source for production of commercial rubber known as NR has proved as the best producer, accepting the highest productivity of the plants with magnificent physical properties of the rubber product (Junian *et al.*, 2015). The oldest known rubber is the polymer of high molecular weight isoprene unit (2-methyl-1, 3-butadiene) (Visakh *et al.*, 2012). Natural rubber latex generally contains about 4%–5% non-rubber constituent consisting carbohydrate, protein, lipids while synthetic rubber is manufactured from petrochemical by products. Another type of rubber is vulcanized rubber, which is prepared by vulcanization process. In the vulcanization process the long chains present in the rubber molecule undergo crosslinking, as a result the weak, soft, plastic material loss these properties and gain the strong elasticity property having high deformability and a great mechanical property. The vulcanization of rubber leads to loss the thickness of rubber and become more resistance towards light, heat and aging process (Visakh *et al.*, 2012).

NR exhibit some favourable properties that leads to its use in very large extent in heavy duty truck, defence industry, aerospace and medical fields (Malas *et al.*, 2014). Other industries which include packaging products such as tapes, films NR is used (Bras *et al.*, 2010). Butadiene Rubber (BR)/styrene butadiene rubber (SBR) blends are used in passenger car radial (PCR) tire compounds. Das *et al.* has done dispersion of multiwalled carbon nanotube (MWCNT) in the SBR/BR blends successfully without any damage of their unique properties and also observed the unproved mechanical properties in comparison of unfilled rubber. Still NR lacks some properties for its utilization in the rubber industries. Due to the unsaturated backbone NR decayed by thermal attacks and ozone (Junian *et al.*, 2015). Another property of NR like low strength become soft in warm weather and brittle in cold lead to limit its use (Visakh *et al.*, 2012). To overcome the limitation many researchers, work on the NR to enhance its property. A study has observed on the remarkable improvement of the storage tensile modulus on filler addition (Bras *et al.*, 2010). Due to the renewable character, biodegradable property, low density, high specific resistance related with certain properties of nanoparticle, the use of reinforcing agent taken from natural source produced a good advantage (Pasquini *et al.*, 2010). Rajisha *et al.* have studied about on the preparation of excellent nanofiller (prepared from nanocrystals). For NR latex and that possess the potential to replace the conventional polymer composite and nanocomposite (Rajisha *et al.*, 2014). Angellier *et al.* has described the improvement in relaxed storage modulus of various weight% with respect to different temperature, filler content in a NR matrix. Dufresene and Caville also have reported about the great reinforcing effect of starch nanocrystals especially at temperature when more than glass transition temperature (T_g) of the matrix (Le Corre *et al.*, 2010). This reinforcing effect can be increased on addition of the filler amount and also on the reduction of particle size (Angellier *et al.*, 2005). Bras *et al.* (2010) has reported that on addition of polysaccharide (starch) to polyethylene lead to the faster disintegration and this mechanism could be utilized also in case of NR to increase its biodegradability faster in presence of polysaccharide (cellulose whisker). For many authors the result of addition of nanofillers is an increase in the tensile strength and also the elastic modulus of the composite together.

The literature regarding the designing of the materials towards imitating the NR with similar characterization and properties is plenty. The materials like polyurethane, silicon etc., have the behaviour of NR. However, the natural and synthetic rubber have the limitation in properties like mechanical behaviour, biodegradability, gas permission and acid base resistance those are challenge for present researchers to overcome these properties. When polysaccharides are incorporated in rubber it gives an interactive compatible composite for enhancement in various properties because polysaccharides are functional biopolymers, those have strong interaction with the functional group of the rubber. Hence, the choice of polysaccharides as incorporating material has greater objective for improvement of important properties of rubber.

Although numerous numbers of articles are reported the literature related to different polysaccharide based rubber composite, however a concise report summarizing all different polysaccharide incorporated rubber composite is scanty in literature. Present article involves the summary related to the reinforcement of polysaccharide such as starch, cellulose, chitosan and dextran.

Types of Polysaccharide Reinforced Rubber

Starch

Starch is the superabundant material found in nature. The occurrence of starch are mainly in stalks, plant roots, staple crops like rice, wheat, corn, potato, tapioca and also from crop seed. Primarily starch produced as flour like white powder after its extraction

Fig. 1 Chemical structure of amylose (a) and amylopectin (b). Reproduced with permission from Xie, F., Pollet, E., Halley, P.J., Averous, L., 2013. Starch-based nano-biocomposites. *Progress in Polymer Science* 38, 1590–1628.

from plants and this powder form is insoluble in cold water. It is a biodegradable, natural, renewable agro polymer which produced by many plants (Le Corre *et al.*, 2010; Tang and Alavi, 2011; Savadekar and Mhaske, 2012; Du *et al.*, 2019; Peres *et al.*, 2016). The starch granules consist of two types of glucosidic macromolecules generally. One is (i) branched amylopectin (ii) essentially linear amylose (Shen *et al.*, 2016). The amylose of starch is defined as a linear branch of α -D glucopyranose linked by (1–4) α -D-glycoside bonds. Amylopectin linked through a high molecular weight consisting of relatively short branches of α -D-(1-4) glucopyranose linking linear chain of α (1→6) linkage (Xie *et al.*, 2013; Paoribut *et al.*, 2015; Ali *et al.*, 2011). The chemical structure of amylose and amylopectin are represented in the Fig. 1 (Xie *et al.*, 2013).

Angellier *et al.* has reviewed about the waxy maize starch nanocrystals which exhibit all the properties to use as reinforcing filler for NR and considered as one of the principle elastomeric unit used in industries (Du *et al.*, 2019). Rajisha *et al.* (2014) has studied a new reinforcing filler for NR prepared from potato starch nanocrystals and this can have creditable contribution towards the development of new green composite and reported that it can be a better replacement carbon black (CB) due to its tremendous strengthening effect like elastic behaviour, stiffness.

Synthesis of starch nanocrystals

In the recent research, starch nanoparticle gain the attention of researchers in number of works which are increasing exponentially for the development of bio composites. A few scientists have studied about the synthesis of microcrystalline starch and starch nanocrystals using acid hydrolysis. The literature (Rajisha *et al.*, 2014) describes the reinforcing effect of starch nanocrystals prepared from potato. The nanocrystals were synthesized by acid hydrolysis with sulphuric acid (H_2SO_4). In the first step of preparation of nanocrystals 36 g of starch granules from potato has taken and 25ml of H_2SO_4 (36 N) mixed for 5 days and remain at 40°C with constant stirring of 100 rpm speed. The aqueous suspension obtained undergoes centrifugation and ultrasonic treatment. Finally, the solid fraction (3.4 wt% weight concentration) of aqueous suspension has obtained. Xu *et al.* (2010) have reported the preparation of corn starch nanocrystals and acetylated starch nanocrystals; the literature also follows the acid hydrolysis method for preparation of nanocrystals.

Properties of starch

Thermal property

Thermogravimetric analysis (TGA) of polymeric material gives a brief knowledge about the thermal stability and polymer composite (Pan *et al.*, 2014; Wu *et al.*, 2018; Senna *et al.*, 2012). Duy *et al.* has studied the thermal property of NR and composites prepared by different method (Duy *et al.*, 2012; Wu *et al.*, 2009). Fig. 2 gives a brief explanation about the TG curves of NR gum vulcanizate, NR/cassava starch (10 phr) composite has prepared by direct blending and also for composite prepared by coagulation and Table 1 outline the summary of thermal degradation from the TGA curve of the composite and NR. The literature has said about no thermal degradation

Fig. 2 TG curve of NR and composites (a) NR; (b) cassava starch (10 phr)/NR composites prepared by direct blending; (c) cassava starch (10 phr)/NR composites prepared by co-coagulation. Effects of filler loading and different preparation methods on properties of cassava starch/natural rubber composites. *Polymer-Plastic Technology and Engineering* 51, 940–944.

Table 1 Thermal degradation of NR gum vulcanization, cassava starch/NR composites with different methods of preparation

Sample	$T_{-5\%}$ ($^{\circ}\text{C}$)	$T_{-50\%}$ ($^{\circ}\text{C}$)
NR	343	397
Cassava starch (10 phr)/NR composite prepared by direct blending	310	386
Cassava starch (10 phr)/NR composite prepared by coagulation	318	399

Note: Reproduced with permission from Duy, N.Q., Rashid, A.A., Ismail, H., 2012. Effects of filler loading and different preparation methods on properties of cassava starch/natural rubber composites. *Polymer-Plastic Technology and Engineering* 51, 940–944.

below 300°C. In between 300 and 450°C all thermal degradation has shown and presence of polyisoprene chain increases the degradation. Although the NR gum vulcanizate at 300°C but maximum decomposition occurs at 450°C while in case of cassava starch if stabilised up to 275°C and at 375°C the maximum decomposition takes place. Thus it leads to failure of thermal stability of composite.

Biodegradable properties

In this literature (Pichaiyut *et al.*, 2016), the increase in biodegradability of rubber on addition of starch has reported by the soil burial test. The amylopectin of starch is more easily undergo broken down by microorganisms than amylose along with hydrolysis rate also higher than amylose and this leads to degradation of starch structure (Pang *et al.*, 2013). The biodegradation test of composite was held by estimating the weight loss percentage of neat rubber and three ternary blends such as unmodified NR (RSS#3), epoxidized NR with 25 mol% epoxides (ENR-25) and 50 mol% epoxides (ENR-50) after 2–6 months buried in soil.

The Fig. 3 gave a brief study about weight loss of neat rubber i.e., RSS#3, ENR25, ENR50, linear low density polyethylene (LLDPE), TPS and the ternary blends of RSS#3/LLDPE/TPS, ENR-50/LLDPE/TPS, ENR-25/LLDPE/TPS. It has been seen that there is 8.73 and 54.05 wt% loss in neat TPS in 2 and 6 months respectively and also show that TPS degrade faster than that of other neat polymers and ternary blends, while LLDPE lost 0.02 and 0.09 wt% in 2 and 6 months respectively which is a very little in amount. The ternary blend of NR/LLDPE/TPS show highest weight loss than that of ternary blend with ENR-25 and ENR-50. This is due to the stronger interfacial interaction. Azura *et al.* have studied effect of sago starch on soil decomposition of NR via enzymatic cleavage and oxidation of poly isoprene backbone as the more feasible biodegradation of starch component in comparison to poly isoprene backbone (Afq and Azura, 2013).

Cellulose

In the present era cellulose is considered as the most abundant renewable biopolymer produced from biomass (Lavoine *et al.*, 2012). Annually the production rate of cellulose has estimated 7.5×10^{10} tons. Wide distribution in higher plants-woods, 50% of which are cellulose content and these are the most important raw source of cellulose. The cellulose also can derive from several marine animals, annual crops and lesser degree in fungi, algae, bacteria (Brinchi *et al.*, 2013). For the preparation of green rubber composite, cellulose has taken the attention of researchers towards itself due to its renewable, low density, low energy consumption, biodegradability, environmental friendliness, and low cost, easy processing properties (Roy and Potiyaraj, 2018). Cellulose is a homo polysaccharide consists of β -D-glucopyranose units. These units are linked together by β -1–4 linkages. Each

Fig. 3 Weight loss of neat rubbers and 50/40/10 ternary blends after burial in soil for 2 and 6 months. Reproduced with permission from Pichaiyut, S., Wisunthorn, S., Thongpet, C., Nakason, C., 2016. Novel ternary blends of natural rubber/linear low density polyethylene/thermoplastic starch: Influence of epoxide level of epoxidized natural rubber on blend properties. Iranian Polymer Journal 25, 711–723.

monomer of cellulose has 3 hydroxyl groups and those groups possess ability to form H-bond and this ability play an important role governing the physical properties of cellulose (Brinchi *et al.*, 2013). Bras *et al.* (2010) has reported about the incorporation of cellulose whiskers into NR, thus the green composite obtained have high thermo mechanical, biodegradable properties and the composite also show resistance to water vapour permeability. Pasquini *et al.* (2010) have obtained report on significant report of storage modulus of composite when cellulose whisker (filler) added to NR.

Synthesis of cellulose nanocrystals

Generally, the 3 hydroxyl group present in polysaccharide nanocrystals impart possibility of various reactions (Prusty *et al.*, 2017). Lam *et al.* (2012) have reported about chemical modification nano crystalline cellulose (NCC) with the help of present hydrolysis groups in the glucose units and reviewed about different application of NCC as a result of chemical modification. Some of the chemical modification of hydroxyl group of NCC is shown in Fig. 4.

The fabrication of CNCs via acid hydrolysis of cotton linter and utilizing it as a reinforcement material for nitrile rubber (NBR) has reported by Cao *et al.* (2013) In this literature small pieces of cotton seed linter pulp has mixed with aqueous solution of sulphuric acid (250 ml, 64 wt%) followed by 2 h of vigorous stirring at 60°C. The suspension thus obtained has washed with water by the help of centrifugation and the suspension undergone purification in terms of dialysis against deionized water to achieve the neutral pH of suspension. As a result, a stable suspension of CNCs has formed after concentrating by evaporation process. The suspension obtained contains 5.0 wt% solid. Finally, it has stored in the refrigerator.

Synthesis of hydrophilic bacteria cellulose whiskers (BCWs) as a result of acid hydrolysis of BC particles was demonstrated by Chen *et al.* (2018) and form nanocomposite with carboxylated acrylonitrile butadiene rubber (XNBR). The literature emphasized on the XNBR/BCW nanocomposite as an attractive candidate for the new type of stimuli responsive material. Johar *et al.* (2012) have reported about the fabrication of CNCs from rice husk. This paper involves preparation of CNCs by three steps as alkali treatment, bleaching process and acid hydrolysis respectively. Bras *et al.* (2010) in this study have demonstrated the preparation of CW from biogases pulp and focussed on the significant improvement of tensile strength and due to addition of CW and also the improvement in young's modulus which is represented in Fig. 5.

The CNCs synthesized by literature (Chuayjuljit *et al.*, 2009) and the method involves the preparation of CNCs by sulphuric acid (H₂SO₄) hydrolysis. At first 2 g of pulp has taken and added with 100 ml of 55 wt% H₂SO₄ at 50°C and followed by mechanical stirring at 300 rpm for 1.5 h. Thus the hydrolysed suspension form has diluted with the help of ice cubes so the reaction stops and then undergoes centrifugation (to wash) and dialysis (to achieve neutrality). The CNC suspension undergoes ultrasonic treatment about 10 min for completion. Finally by freeze drying process the CNC powder has collected.

Properties

Mechanical property

The mechanical loss factor ($\tan\delta$) and the log of the storage modulus i.e., $\log(E'/\text{Pa})$ of NR films reinforced with different wt% (0,2,5,7) CWs which are extracted from cassava biogases following 2 produces (CW₂₀ & CW₄₀) as a function of temperature are explained in Figs. 6 and 7. The storage modulus of unfilled NR gives a constant graph at 1 GPa on increasing the temperature. At

Fig. 5 Tensile strength and modulus of rubber/ cellulose whiskers nanocomposites film as a function of composition. Reproduced with permission from Bras, J., Hassan, M.L., Bruzesse, C., *et al.*, 2010. Mechanical, barrier and biodegradability properties of bagasse cellulose whiskers reinforced natural rubber nanocomposites. *Industrial Crops and Product* 32, 627–633.

–60°C a sharp decrease in the glass rubber transition is reported. The rubbery modulus has decreased slightly till 1 MPa & at 1 MPa it remains almost constant in the neat matrix or else the mechanical loss factor is observed around –55°C, which evidenced the relaxation process also it is seen that on addition of CW the magnitude of $\tan\delta$ peak decreases (Fig. 6). The rubbery relaxed modulus value and main relaxation processes temperature value (T_α) has reported in Table 2.

Fig. 6 Evolution of the loss angle $\tan \delta$ as a function of temperature at 1 Hz for NR films reinforced with 0(●), 2(○), 5(▲), 7(△) and 10 wt%(+) cellulose whiskers obtained according to hydrolysis condition CW₂₀(a) and CW₄₀(b). Fig. 7 Evolution of the logarithm of storage modulus as a function of temperature at 1 Hz for NR films reinforced with 0(●), 2(○), 5(▲), 7(△) and 10 wt%(+) cellulose whiskers obtained according to hydrolysis condition CW₂₀ (a) and CW₄₀ (b). Reproduced with permission from Pasquini, D., de Morais Teixeira, E., da Silva Curvelo, A.A., Belgacem, M.N., Dufresne, A., 2010. Extraction of cellulose whiskers from cassava bagasse and their applications as reinforcing agent in natural rubber. *Industrial Crops and Products* 32, 486–490.

On addition of cellulosic nanoparticles an insignificant increase in T_g while a significant increased rubbery modulus and increased reinforcing effect has observed. [Pasquini et al. \(2010\)](#) have found the relative modulus of the nanocomposite around 46 for CW₂₀ and 70 for CW₄₀ respectively. The storage modulus remains constant and it is mainly due to the restriction of molecular motion to vibration and also to the short range molecular motion at glassy state ([Visakh et al., 2012](#)).

Thermal properties

The TGA and differential thermo gravimetric (DTG) plots of NR/CW composites ([Visakh et al., 2012](#)) are reported in [Fig. 8 \(a\)](#) and [\(b\)](#) respectively. TGA estimates the weight change of the material on heating in presence of air. At lower temperature when rubber compound heated firstly the evaporation of volatile components mostly moisture took place & further heating cause degradation of polymer part this lead to weight loss as shown in curve. The plot- 8(a) gave information about TGA analysis of NR and NR/CW nanocomposite having 2.5, 5 & 10 wt% of whisker content. For NR the beginning of degradation takes place around 260°C and undergo a constant shift to 273, 276, 278°C for the nanocomposite having 2.5, 5, 10 wt% CNWs respectively with increase cellulose nanowhiskers (CNW) concentration to 10 wt% the first degradation peak of NR increased from 275°C to about 350°C ([Fig. 8\(b\)](#)). When the cellulose whisker added to the composite it has been observed that the thermal stability along with de composition temperature increases at different stages ([Fig. 8\(b\)](#)).

Table 2 Main relaxation temperature (T_{α}) and storage tensile modulus (E') estimated at 25°C for NR nanocomposite samples

Hydrolysis time (min)	Whisker content (%)	T_{α} (°C)	E' (25°C) (MPa)
20	0	-55.4	2.2
	2	-56.2	13.7
	5	-56.6	23.0
	7	-57.5	73.8
40	10	-58.6	102.2
	2	-55.9	9.8
	5	-56.1	33.4
	7	-56.9	41.1
	10	-58.9	153.9

Biodegradation property

Generally, NR undergoes degradation by nature in a slow process. [Bras et al. \(2010\)](#) studied about the increase in degradation speed of NR on addition to CWs as biodegradable nanocomposite plays an important role in the area of packaging materials. The biodegradable property of the samples was done by buried the sample in soil ([Chuayjuljit et al., 2009](#)). The result of biodegradation analysis of rubber on reinforcement of CW is depicted in [Fig. 9](#).

The graph said about the difference in weight loss in between neat rubber and cellulose containing nanocomposite. The neat NR undergoes 19% weight loss while NR with 7.5 & 12.5 wt% of CWs undergo 62 & 71% weight loss respectively after 4 weeks. Presence of cellulose component in the nanocomposite leads to increase in porosity, loss of the integrity, void formation of the rubber matrix which result quicker disintegration of nanocomposites having CWs than neat rubber matrix ([Yang et al., 2014](#)).

Chitosan

Chitosan is a bio decomposable and biocompatible polymer with a vast structural possibility for its modification (chemically and mechanically) to generate unique functions and properties in biomedical and other fields ([Mao et al., 2010](#); [Nagpal et al., 2010](#); [Prabaharan, 2014](#); [Shukla et al., 2013](#)). The primary $-NH_2$ present in chitosan structure is very useful in case of pharmaceutical application than other natural polymers. The glycosidic bond present in chitosan structure is unstable in acidic medium thus it can be hydrolysed under acidic environment which cause the decrease in viscosity and molecular weight ([Shukla et al., 2013](#); [Arya et al., 2007](#)).

[Nagpal et al.](#) have studied various properties of chitosan which makes the biopolymer has a very shining future in pharmaceutical nanotechnology area. Due to the absorption enhancing effect of chitosan it did improvement of the drug bioavailability & its nano size helps to facilitate the drug delivery through the cell membrane ([Nagpal et al., 2010](#)). The various properties of chitosan depend on the degree of deacetylation, molecular weight & viscosity. Chitosan having low degree of deacetylation are reported as the active absorption enhancer of both high & low molecular weight. Due to better stability of chitosan nanoparticle

they offer many advantages (Prusty *et al.*, 2017; Arya *et al.*, 2007). Many applications of chitosan nanoparticle has studied by scientists like in case of parental drug delivery, non-viral gene delivery, brain targeting, vaccine delivery, insulin delivery, electro deposition, stability improvement, pre-oral administration, mucosal drug delivery, ocular drug delivery, controlled drug delivery, tissue engineering, & increase of antioxidant, biosensors, food packaging, membrane & medicine (Shukla *et al.*, 2013; Arya *et al.*, 2007; Jayakumara *et al.*, 2010).

Preparation of chitosan nanocrystals

Among many synthetic and natural polymers available chitosan is broadly studied in case of preparing both micro and nano particles for drug encapsulation (Arya *et al.*, 2007). Although, $-NH_2$, $-OH$ group present in chitosan structure primarily provides basis of interaction with other molecules & polymers. Modification of chitosan such as nitration, alkylation, thiolation, azylation and some other modification is shown in Fig. 10 (Shukla *et al.*, 2013).

Different method has been put forward to synthesize chitosan macro/nano particles such as precipitation, evaporation, ionic gelation, spray drying, electro spraying (Arya *et al.*, 2007). Other method of preparation of chitosan nanoparticles extensively have studied by Nagpal *et al.* (2010) which include micro emulsion, emulsification-cross linking, polyelectrolyte complex, solvent

Fig. 9 Bio-disintegration of rubber/cellulose whiskers (CW) nanocomposites in soil for up to 4 weeks. Reproduced with permission from Bras, J., Hassan, M.L., Bruzesse, C., *et al.*, 2010. evaporation methods, complex coacervation. Saharan *et al.* (2013) have demonstrated the chitosan nanoparticles preparation by doing modification of ionic gelation method of chitosan with tripolyphosphate (TPP) anions. In this method chitosan taken has dissolved in 1% acetic acid (0.1% level) & then placed in a magnetic stirrer for overnight stirring at 200 rpm followed by filtration through poly vinyl dine difluoride membrane syringe filler with 0.22 μm pore size. After that chitosan undergo crosslinking with TPP anion at equal volume in a magnetic stirrer and the stirring process was done at 700 rpm. The resulted mixture has placed to centrifugation for 10 min thus the re-suspension of pellet was took place and finally undergo ultra-sonication. 3 times repeatedly this process of centrifugation followed by ultra-sonication was done and thus the formed precipitate was stored at 4°C. The chitosan microsphere preparation by ion induction & chemical crosslinking has reported by Ming-zhe *et al.* (2017).

Properties

Tensile properties

The tensile property of NR & its vulcanizes depends on crosslinking density (Rubentharen *et al.*, 2015), degree of crystallization and degree of filler addition (Ming-zhe *et al.*, 2017). The effect of different amount of chitosan (CTS) content on the tensile property of chitosan epoxidized natural rubber (CTS-t-ENR) biocomposites is represented in the Fig. 11. The tensile strength of CTS-t-ENR increases up to 5 phr & thereafter a decrease in tensile strength noticed due to the strong interpretation of polymer-filler. CTS-t-ENR blend having 2.5 & 5 phr chitosan content show uniform dispersion in ENR matrix but at 10 phr tensile property decreased as CTS undergo aggregation causing agglomeration in the ENR matrix. As the literature said when filler amount overcome the critical value the aggregation develop which lead to break down of the new material along with reduction of the properties (Rubentharen *et al.*, 2015). Fig. 12 represented the percentage elongation break with chitosan loading up to 2.5 phr homogeneous filler formation became tougher & thus there is matrix-filler interaction become poor. As the chitosan content increases the overall modulus also increases this could be viewed from the Fig. 13. Thus it could be drawn out chitosan provide a better strengthening effect to the rubber.

Fig. 11 Tensile strength of (i) CTS-t-ENR (with CTS loading of 0, 2.5, 5, 10 and 15 phr) and (ii) 5 phr CTS-t-ENR. Reproduced with permission from Raju, G., Haris, M.R.H.M., 2016. Thermal property

Thermal decomposition analysis is meant to evaluate the thermal stability of NR/chitosan (CS) blends (Venkatanarasimhan and Dhamodharan, 2015). Figs. 14 and 15 are the TGA & DTG curve of NR, CS, NR/CS blend, NR/CS (34%). The degradation temperature at 10% & 50% along with the residual char amount at 900°C was described in Table 3. In comparison with NR CS possess poor thermal stability and the literature also said that CS initiated at about 305°C, where the NR have higher thermal stability than CS and its decomposition initiating at 385°C. Also there was significant mass loss of NR-CS (34%) graft copolymer commences above 420°C (Table 3). This degradation temperature of the NR/CS (34%) is extremely higher than that of CS and also upgraded by 35°C that of the NR. The TGA & DTG studies validate about the grafting reaction of CS on the NR matrix raises the thermal stability of both NR & CS.

Degradation Properties

Undoubtedly NR has huge limitation of very low degradation property. So addition of polysaccharide helps to increase the degradability of NR. The test was done by taking samples of high ammonia concentration latex (HA) without filler; chitosan filled HA, fresh latex (FL) without filler. Chitosan filled FL and shrimp shell filler with NR. The entire matrix prepared with 20 wt% of filler. Then by taking an acrylic box the test was done. The NR without filler on the surface of soil & the underground sample found still sticky after the degradation test, this result indicate chitosan impart degradation effect on the NR/chitosan composite on the surface of soil. The polysaccharide based rubber nanocomposites can be prepared by various reported methods such as mechanical mixing, *in situ*, blending, latex blending, coagulation, acid hydrolysis and dipping techniques. Preparation, characterization, and properties of different polysaccharide based rubber nanocomposites have been reported elsewhere. These are summarized as Table 4.

Conclusion

Rubber nanocomposites are a new class of elastomeric materials with a future promise of potential applications as high-performance materials. These articles are mainly focused on the preparation of different polysaccharide based nanostructures like starch nanocrystals, cellulose nanowhiskers and chitosan nanocrystals and their successful reinforcements to the natural rubber towards the development of biodegradability along with improved mechanical, thermal, rheological and anti-bacterial behaviors. It is noticed that the biodegradable properties of rubber is achieved by dispersion of different kind of polysaccharide based nanostructures like starch nanocrystals, cellulose nanowhiskers and chitosan nanocrystals without much compromise with other properties. The main scope of the present article relevant to the equal distribution of different polysaccharide based nanostructures like starch nanocrystals, cellulose nanowhiskers and chitosan nanocrystals and improving the strong interfacial adhesion between starch nanocrystals, cellulose nanowhiskers and chitosan nanocrystals and rubber. As natural rubber is obtained from renewable resource so it is not economic than different polysaccharide based nanostructures like starch nanocrystals, cellulose nanowhiskers and chitosan nanocrystals. So nanocomposites of natural rubber and different polysaccharide based nanostructures like starch nanocrystals, cellulose nanowhiskers and chitosan nanocrystals will become emerging future materials.

The Potential of Environmental-Friendly Biopolymers as an Alternative to Conventional Petroleum-Based Polymers

Farooq S Al-Jahwari and Tasneem Pervez, College of Engineering, Sultan Qaboos University, Muscat, Oman

© 2020 Elsevier Inc. All rights reserved.

Introduction

Polymers have become one of the most important class of materials nowadays because of their fascinating properties and ease of manufacturing. Thermoplastics can also be recycled which make them environment-friendly. However, the source of most plastics up-to-date is the petroleum industry. It is understood that fossil fuels are the main reason for CO₂ emissions (Liddle and Sadorsky, 2017) and hence efforts are made to find other sources of polymers. Unfortunately, it is difficult to replace polymers with metals or ceramics due to many reasons. One of the reasons is that polymers can be processed at relatively low temperatures compared to metals, which induces less energy requirements and hence relatively much less infrastructure for manufacturing. One of the toughest polymers is polycarbonate which can easily be processed at around 250°C. In contrast, the processing temperature of aluminum is about 610°C for the sintering process only without even reaching to the melting point (Issa *et al.*, 2017). Another interesting feature of polymers is their viscoelastic response which is important for damping and sealing applications.

Since polymers are an important class of material for today's applications, searching for an environmental-friendly alternative of petroleum-based polymers becomes a necessity due to the adverse effects of utilizing fossil fuels on our environment. Petroleum-based polymers are characterized with excellent thermal stability and mechanical properties compared to bio/bio-based polymers. For example, the glass transition temperature of polylactic acid (PLA), which is a biopolymer derived from renewable resources such as corn starch, tapioca roots, chips or starch, or sugarcane, is around 56°C, while the softening temperature is about 105°C for acrylonitrile butadiene styrene (ABS), which is one of the most commonly used thermoplastic petroleum-based polymers. Nevertheless, biopolymers are the safest choice for bio-applications due to their biocompatibility and acceptable thermal range. Luo and Hu (2017) reviewed variety of works on biopolymer-based nanoscale nutrient delivery systems to avoid any side effects or toxicity and to maximize their effectiveness to boost bioavailability of encapsulated nutrients. Biopolymers can also be used for structural application if being fabricated either as porous structures or part of a composite material. The applicability of biopolymer-based composites in developing construction materials for architecture designs was proven by Dahy (2017). For thermal applications such as solar thermal collectors, biopolymers have shown the potential to replace aluminum and copper as absorber materials (Klein *et al.*, 2017).

Two case studies are presented in this article to illustrate the potential of two biopolymers for structural applications and damping attenuation, namely, polylactic acid (PLA) which is a biopolymer and green high density polyethylene (GHPE) which is a bio-based polymer. The green high density polyethylene is made by consuming CO₂ from the atmosphere. The first case study presents the development of functionally graded porous structures made of polylactic acid and their potential as light weight but strong porous materials. The second case study, presents a bio-composite made of green high density polyethylene blended with waste rubber and thermally activated microspheres for the application of impact absorption. Both studies proved the potential of bio/bio-based polymers and composites for structural and damping applications, and hence, potentially, may replace conventional petroleum-based polymers.

Material Structures of Biopolymers for Enhanced Strength and Damping

As mentioned earlier in the article that biopolymers have the limitation of less mechanical strength and low thermal stability compared to the petroleum-based polymers. This statement is true for raw materials, but biopolymers can be fabricated in specific structures that can enhance the mechanical properties. Fabrication of such structures, as will be discussed later, may also contribute to alleviate the thermal instability issue to some extent. Certainly, if petroleum based polymers are fabricated in these specific structures, they will outperform biopolymers, but the objective here is to develop biopolymeric structures that can replace the current petroleum-based polymeric products in the market and not competing with the strength. Three structures are believed to explore the potential of biopolymers as structural components, namely, hierarchical structures, functionally graded porous structures, and multiphase green composites with thermally activated microspheres. Combination of the three classes of material structures is capable of producing superior materials for a variety of engineering applications like structural design and impact absorption. This article will take particularly these two applications as examples where biopolymers can be tailored for high performance.

Hierarchical structures can be used for tailoring the properties and monitoring failure at multiple length scales, which are especially prominent in applications like impact attenuation. Additionally, functionally grading the material results in continuous spatial-temporal variation in the microstructural properties. This eliminates the presence of interfacial weakness due to discontinuous boundaries. The properties of functionally graded polymeric based hierarchical structures can be tailored from nano-scale all the way up to the microstructural level using thermo-mechanical and chemical processing methods. Due to the

visco-elastic/plastic nature of polymers in general, biopolymeric material structures can be manufactured with appreciable energy absorption capability using intrinsic and extrinsic mechanisms while providing energy dissipation to reduce shock during impact, for example. Specifically, besides tailoring of the material properties, advantage will be taken of the spatial-temporal state of the system. As a result, failure propagation will be resisted not only by the intrinsic properties (e.g., visco-plastic dissipation) but also by extrinsic factors like controlling crack propagation pathway and strain energy absorption through increase of internal degrees of freedom (e.g., buckling or rotation of internal cell walls in the case of porous structures).

Nature Inspiration of Material Structures

Development of high performance hierarchical structures may come from the designs existing in nature itself. Widespread examples include the clubs of mantis shrimps, nacre-like structure in sea shells, and bone. A characteristic feature in all these structures is high stiffness but also high deformation at large stresses. Stiffness and toughness of a material are normally exclusive properties. The reason is that stiffer materials have lower ability to flow and relax internal stress. As a result, when the internal stresses at high stress point like crack tips exceed failure strength, the material fails with very little resistance. On the other hand, materials which have the ability to flow and relax stresses usually display poor stiffness and lower absolute strengths. The exception is high density materials like metals which may display high stiffness and toughness due to the larger number of molecules or bonds per unit volume. However, in many cases, it is undesirable to use high density materials due to power and efficiency limitations.

Intrinsically, it is difficult to find high strength, toughness, and low density all in one material. For obtaining the most optimal combination of these characteristics, extrinsic reinforcement systems must be employed. For high toughness, rupture of molecular bonds should be minimized and frictional flow between molecules should be promoted. But as discussed, too much flow can also result in reduction of stiffness. For obtaining the optimal balance, it is possible to have an extrinsically reinforced system which does not allow sliding at low stress but promotes sliding at high stresses to minimize cleavage of the material (Fig. 1). An example of a flawless incorporation of such system design can be found in sea shells. These are nacre like structures which are made up of three dimensional brick and mortar layout. The bricks here are composed of hard hydroxyapatite substances of sub-micrometers in dimension. The mortar is made of soft organic materials which act as a high strength glue to hold the bricks together. In addition to this, mineral bridges and nanoscale-asperities exist between the bricks. At low stress, these bricks support most of the load and hence the structure has a high stiffness response. At higher stresses, instead of the bricks cleaving apart, the interface dissipates energy across many length scales – from molecular level viscous sliding of the organic glue to breaking of nano- and micro-scale asperities and bridges. These nacre-like structures have been used as inspiration for the development of synthetic lightweight ceramic structures with toughness on the order of some aluminum alloys. Another example is bone, which is functionally graded foam with a solid outer shell and a soft inner core. Multiple dissipation mechanisms from nanoscale sliding of crystals to crack bridging results in bone displaying greater ductility than steel despite being composed of very brittle hydroxyapatite molecules. It is such intrinsic and extrinsic reinforcement mechanisms which results in effective properties of hierarchical materials far above the individual components.

Why Polymers?

Polymers are simply assemblies of chains composed of various side groups along carbon-carbon backbone bonds. The backbone bonds composed of carbon linkages are extremely stiff. During deformation upon application of load, strain energy is stored in both the bond stretching and chain sliding. Due to the large amount of frictional sliding between molecules (chains), polymers usually display low specific modulus as compared to other classes of materials (ceramics or metals). However, they also display higher specific toughness or impact resistance than most other material classes. Because of their low density, polymers usually display low strength on a per-unit volume basis. In order to effectively utilize the inherent benefits of polymers for impact

Fig. 1 Healthy human cortical bone resists fracture through complementary intrinsic and extrinsic contributions. Reproduced from Wegst, U.G.K., Bai, H., Saiz, E., Tomsia, A.P., Ritchie, R.O., 2014. Bioinspired structural materials, *Nature Materials* 14, 23.

resistance while maintaining strength and stiffness, it may be necessary to extrinsically reinforce polymers with the addition of filler materials. These fillers may be polymer-based or from other classes of materials. Numerous studies have shown the potential of filler reinforcement to improve properties of the resulting polymer based composites beyond the individual components as a result of hierarchical reinforcement mechanisms. Nano-polymer composites are also another class of composites with high interest. In these composites, one of the phases is in the nanometer dimensions. This results in multi-scale reinforcement mechanisms acting to retard crack propagation and improve toughness.

Functionally Graded Porous Composites

Continuous fiber reinforced composites have been used as an alternative to high strength metals in order to reduce weight and improve the specific load bearing capacity. They are primarily composed of mats of aligned fibers impregnated with a resin adhesive to bond and facilitate load transfer between adjacent fibers. The high degree of alignment and aspect ratio of the fibers permit utilization of a large portion of the fiber's inherent strength and stiffness. Aligned carbon fiber-epoxy composites for replacement of metal structural components have been of interest in the defense aviation and recently, commercial aviation sectors. While these composites provide very high strength and weight reduction, they are low in impact resistance due to the relatively brittle nature of both epoxy and carbon fibers. Of high interest in research is the development of bio-inspired intrinsic and extrinsic dissipation mechanisms in composites such that the overall strength is suitably maintained while significantly improving impact resistance.

Introducing porous structures can significantly reduce the weight further and potentially improve the toughness of polymers by increasing the complexity of failure or crack propagation. Additionally, the thin walls of foams can increase localized plane stress condition at the cell walls which acts to improve the toughness. The increased internal rotational and translation degrees of freedom of the foam cells also act to retard crack-propagation. These extrinsic reinforcing mechanisms in foams result in higher specific properties than the fully solid counterparts. The properties of foams are entirely dependent on its microstructure which has two main characteristic features – the cell size and the void fraction both of which can be controlled dependently or independently depending on the processing route.

Functionally graded structures have the potential to combine the benefits of all the above mentioned material systems in a continuous spatial-temporal variation that is advantageous in critical loading conditions. This has the benefit of eliminating discontinuous boundaries in a graded material. Discontinuous boundaries in conventional composites weaken the effect of hierarchical reinforcement. An example is functionally graded foams which can have properties superior to honeycombs. In a functionally graded foam, the porosity (void fraction) from the outside layer (solid) to the inside layer (foam) is continuously varied. In contrast, honeycomb structures often display sharp and discontinuous interfaces between the outside skin and the inside hollow core which creates natural sites of weaknesses.

Recyclability and Reproduction of Virgin Biopolymers

At the end of biopolymeric products, the goal is to close the loop and recycling the product to be reused whether as a secondary raw material or reproduce the virgin biopolymer by polymerization from the recycled monomers. The recycling can be broadly classified to mechanical recycling, organic recycling or composting, and chemical recycling or feedstock recovery. In mechanical recycling, the molecular structure of the precursor biopolymer is not broken but rather re-processed to new products through conventional techniques. However, the molecular chain is broken in the case of composting to biomass in addition to water and CO₂ or to the basic monomeric building block of the precursor biopolymer as in the case of chemical recycling.

For mechanical recycling, bio-based polymers and biopolymers can be recycled as most conventional thermoplastics but it need to be recycled in separate streams for each material type. The recycling stream for a specific type of conventional plastics (e.g., Polyethylene (PE) or Polyethylene terephthalate (PET)) can be used to recycle their counterparts of the bio-based alternatives like bio-PE and bio-PET. [Fig. 2\(a\)](#), ([European Bioplastics e.V, 2017a](#)) shows the general steps for typical mechanical recycling. In this type of recycling, the bio/bio-base-polymer is recycled into a new (secondary) raw material without altering the basic molecular structure of the precursor polymer. The bio-wastes are collected and segregated according to the material type through some techniques such as near infrared spectroscopy (NIR), laser or x-ray beside other techniques. After cleaning and grinding the bio-waste, it is recovered to new products by conventional processing techniques through direct melting or pelletizing at first before further processing.

Organic recycling or composting is another route for sustainability of biopolymers where biodegradation takes place under certain aerobic conditions within a specific period of time. Microbes, like bacteria or fungi and their enzymes, are able to digest the chain structure of compostable bio/bio-based-polymers as a source of nutrition. The speed of biodegradation depends on the temperature, humidity, and the number and types of microbes. The typical range of temperature for an industrial composting process is 50–70°C. All those requirements are given in industrial composting facilities to convert compostable plastic products into CO₂, water and biomass ([European Bioplastics e.V, 2017b](#)).

In chemical recycling, ([The Bioplastics Guide, 2016](#)) biopolymers cannot only be melted and used as granules again in a new application, but they can also be broken down into its starting chemical building block, the monomers. The monomers are used as the feed to the polymerization process to synthesize virgin biopolymer. For example, Lactic acid can be recovered from PLA and

Fig. 2 Recycling processes for biopolymers. Reproduced from (a) European Bioplastics e.V., 2017a. Recycling. Available at: <https://www.european-bioplastics.org/news/publications/>. can be again used to make PLA resin. The exciting fact about chemical recycling is that same polymer from different products can be recycled all together to produce the precursor monomer. This process has the advantage of producing virgin polymers in addition to the cost reduction. Chemical recycling seems to be the future trend in polymers recycling with ongoing research efforts.

Case Study 1: Functionally Graded Porous Structures of PLA for General Structural Applications

Fabrication techniques of porous materials, in general, include but not limited to solvent particulate leaching (Shastri *et al.*, 2000; Harris *et al.*, 1998), gas foaming (Harris *et al.*, 1998; Nadella *et al.*, 2005; Zhou *et al.*, 2011), co-continuous melt blending (Yuan and Favis, 2005, 2004; Yao *et al.*, 2009; Pötschke and Paul, 2003; Singh *et al.*, 2004; Zhang *et al.*, 2010), and rapid prototyping (Landers and Mülhaupt, 2000; Ang *et al.*, 2002; Hoque *et al.*, 2005). However, the combination of those techniques lead to more control of the pores growth (Nadella *et al.*, 2005; Zhang *et al.*, 2010), and better mechanical properties (Harris *et al.*, 1998). Nadella *et al.* (2005), fabricated a closed-cell functionally graded PLA by annealing gas foamed samples with a temperature gradient rather than quenching in a bath of uniform temperature. The process of fabricating FG PLA porous structures in this case study is adopted from the work of Nadella *et al.* (2005) on constrained foaming. Details of the fabrication process can be referred to previous work of the author (Jahwari and Naguib, 2016) but will be summarized here.

Hydraulic compression mold was used at 185°C and 3 tons pressure to make the plate-like samples of PLA. The samples were then placed in a pressurized chamber of carbon dioxide (CO₂) at 400 psi for 48 h. CO₂ is the physical foaming agent in this process. The pressure and time of saturation are being selected based on previous experience with PLA to assure enough quantity of the physical blowing agent being dissolved. Skin layer can be formed if the samples left at atmospheric pressure for some time (desorption) after the 48 h of pressurizing in CO₂. However, the samples in this case study were annealed between two hot platens at different temperatures without desorption immediately after the pressure is released. The higher temperature is denoted as T_H and the lower temperature by T_L in the remaining of the text. The minimum of platens temperature is the glass transition point of PLA (56°C). This causes a gradual distribution in pores' sizes and density because of the induced thermal gradient. The pores grow bigger in size from the platen of lower temperature to the platen of higher temperature.

The functionally graded PLA had been fabricated successfully with a gradually changing porosity as shown in Fig. 3. The microstructure is observed to be of three main zones starting with large pores at the side of higher temperature (zone 1), then having a transition region with pores' sizes shifting to smaller pores (zone 2), then a sudden drop of porosity with pores distributed in islands-like structure but with much smaller pores than zones 1 and 2 (zone 3). The SEM images shown in Fig. 3 are for T_H = 130°C, T_L = 80°C and 5 min annealing. Zone 3 dominated 77% of the sample thickness. The remaining 23% of the thickness was for zones 1 and 2 combined.

The relaxation modulus as shown in Fig. 4 was obtained experimentally from the relaxation test for solid PLA, homogeneous porous PLA, and the 130–80°C functionally graded PLA (Fig. 3). Functionally graded PLA shows higher values for the relaxation modulus compared to the homogeneous porous PLA plates which is due to the gradient of pores distribution. The drop in relaxation modulus for the FG PLA is 8.44% only while it is 46.72% for the homogeneous case compared to the solid PLA sample.

Fig. 3 Functionally graded PLA for $T_H=130^\circ\text{C}$, $T_L=80^\circ\text{C}$, and 5 min annealing (porosity = area of all pores/total area). Reproduced from Jahwari, F.A., Naguib, H.E., 2016. Analysis and homogenization of functionally graded viscoelastic porous structures with a higher order plate theory and statistical based model of cellular distribution, *Applied Mathematical Modeling* 40, 2190–2205.

The density of solid PLA is 1.24 g/cm^3 but it is measured to be 0.9052 g/cm^3 for the FG PLA. The drop in density for the FG PLA is 27% while the drop in relaxation modulus is 8.44% only. However, for the homogeneous porous PLA, the density drop is 29.063% only compared to 46.72% drop in the modulus. This is a clear evidence to show the potential of FG porous biopolymers as light weight but strong structures that can find a wide range of applications in many industries like automotive and aerospace load bearing members.

Case Study 2: Bio-Composites Made of Green HDPE for Impact Attenuation

In this case study, composites of Green High Density Polyethylene (GHDPE) and Ground Tire Rubber (GTR) were fabricated by using compression molding technique. Thermally activated microspheres were used as the mean to introduce a porous structure in the composite. The samples were made to test the impact absorption of the bio-composites according to ASTM D5420–10 by dropping a mass of 3.63 Kg (8 lb) from height of 0.635 m (25 in.). The experimental set up shown in Fig. 5 was developed to measure the residual impact load at the receiver side rather than at the impacted surface as done conventionally. The purpose of this setup is to pay more attention to the impact force transmitted across the material towards the receiver. The material is then designed to minimize the transferred force while keeping reasonable level of deformation. Fig. 5(b) shows a sample of the force output. There is a peak of the force at the time of impact which is considered as the transferred load to the receiver.

A strike-face (the face of the material structure which faces the striker) made of polyurethane and 5% silicon carbide was used to protect the porous structure from damage by the striker during impact. The polyurethane/silicon carbide sheet was attached to all the samples in order to compare the effect of GTR to porous structure in terms of energy absorption. The difference in

Fig. 6 Transferred acceleration from impact of rubber and porous base polymeric systems. Reproduced from Jahwari, F.A., 2016. Development and Modeling of Functionally Graded Porous Structures and Composites (PhD), Canada: Department of Mechanical and Industrial Engineering, University of Toronto.

transferred G's (the ratio between the transferred impact load and striker mass) between pure GHDPE and the corresponding composite with 10% GTR was negligible as can be seen in Fig. 6. This could be due to the strike-face that is a rubber-like material which hindered the effect of rubber particles. In contrast, the porous structure with 10% microspheres loading reduced the transferred acceleration by about 28% even with the strike-face. In a functionally graded porous structure, the strike-face can be integrated as part of the system which eliminates the possibility of delamination as well as ease of processing. This result proves the potential of bio-composites to be used for impact absorption and possibly replace the petroleum-base dampers. GTR is waste tires rubber which cannot be recycled and hence is harmful to the environment. The bio-composite developed in this case study, re-used GTR as a damping filler in a new composite material, which can have a wide range of applications in energy absorption systems.

Introduction

Polyether-ether-ketone (PEEK) has certain matchless advantages like its superb biocompatibility, markedly lower weight compared with conventional implant materials, lower tendency to absorb water, excellent mechanical properties, and thermal stability up to 400°C. By utilizing the advantages of additive manufacturing, it is possible to produce an implant according to patient specific contours and needs (Haleem and Javaid, 2019). PEEK has been sulfonated to serve the purpose of drug delivery. But sulfonated PEEK has compromised cytocompatibility, probably due to dispersion of sulfonic compounds in near vicinity. Also sulfonated PEEK shows lower rate of cell proliferation when compared against normal PEEK (Brum *et al.*, 2019). When smooth PEEK is compared against porous PEEK and titanium coated PEEK, then it is found that osseointegration results are superior for porous PEEK (Torstrick *et al.*, 2018). It has been reported that when PEEK is reinforced with short fibers of carbon and glass, that is, short carbon fiber-PEEK and short glass fiber (SGF)-PEEK, it is found that compressive strength comes out to be more for composites than neat PEEK. The failure mode in both types of composite is debonding of matrix–fiber interface. The fibers seem to have been pulled out of the matrix. If SGF-PEEK specimens are made one time by extrusion and another time by injection molding, it is found that extruded specimens possess lower value of toughness than injected ones (Chen *et al.*, 2019). Some studies suggested that if PEEK is coated with pure magnesium, a rise in antibacterial action has been observed (Yu *et al.*, 2018).

Fused deposition modeling (FDM) has marked its presence in the competitive manufacturing technologies owing to its relatively lower costs, versatility in hardware configuration, and capability to process a variety of materials. On reinforcing carbon nanotubes in PEEK, no sufficient impact on mechanical behavior is realized (Berretta *et al.*, 2017). During FDM of PEEK, it is found that diameter of the extruded filament depends upon the melt pressure and surface morphology of the extruded filament is also a function of melt pressure. It is observed that a defect-free surface tends to be produced when melt pressure is appropriately high (Geng *et al.*, 2019). In FDM, when raster angle is 0° and 90° while printing in horizontal (H) direction and when raster angle is 90° while printing in vertical (V) direction, it is observed that the best performance in fracture, tensile, and flexural tests comes out for H0°, then for H90°, and finally for V90° (Arif *et al.*, 2018). When carbon fibers are reinforced in PEEK (CF-PEEK), it is observed that there occurs a drop in density of printed composite material owing to presence of porosity and imperfections among adjacent layers (when taken in comparison against cast counterparts). The cast specimen shows relatively higher thermal conductivity and diffusivity when taken in comparison with the printed composite. Taking the advantage of FDM, anisotropy in thermal characteristics can be obtained according to user specific needs. But this is not possible in cast counterparts (Stepashkin *et al.*, 2018). The reported literature outlined that most of the work done so far has been focused to analyze the mechanical behavior from standard test specimens only and little has been done to test end-use products. When the question of optimization arises, studies take into account only the process parameters. Instead, optimization should comprise of all the factors including polymer type, 3-D printer type, along with process parameters. The mechanical performance can be boosted by employing a negative raster-raster air-gap. While extensive research has been done on certain process parameters, parameters like bed temperature and nozzle temperature have not been properly investigated (Popescu *et al.*, 2018). When annealing is performed on the PEEK printed specimens, it becomes clear that no marked effect is produced in the properties (Tseng *et al.*, 2018). If a coating of nanoparticles of silver is applied onto PEEK, it becomes clear that rate of cell proliferation and antibacterial activity is appreciably good (Deng *et al.*, 2017). PEEK finds applications in dental prosthesis, bone substitution, interbody spinal fusion, treatment of skull bone, and regenerative medicine. Some studies reported the investigations of tensile strength in PEEK-hydroxyapatite composite report an improvement in tensile strength (Yang *et al.*, 2017; Vaezi *et al.*, 2018; Singh *et al.*, 2019). In recent reported studies 3D printing of PEEK was performed with high-end commercial printers. But hitherto very little has been reported on the use of low cost FDM setup with small alteration in print head hardware for printing PEEK based functional prototypes. The functional prototypes prepared were subjected to mechanical, rheological, and thermal stability investigations to ensure their stability in various engineering applications.

Methodology

Fig. 1 shows the methodology for 3D printing of PEEK on low cost FDM setup. The PEEK thermoplastic granules were procured from local market and processed at 430°C temperature on single screw extruder to prepare a feed stock filament of diameter 1.75 ± 0.05 mm. The in-house prepared feed stock filament of PEEK was fed to the FDM printer. In this study a PRUSA printer (Prusa i3 MK3S kit) with alteration in print head (temperature range up to 430°C) was used.

Fig. 1 Methodology for 3D printed polyether-ether-ketone functional prototypes.

Fig. 2 Melt flow index tester.

Experimentation

Melt Flow Index

PEEK has been tested for melt flow index (MFI) using ASTM D1238 standard. A load of 2.16 kg was applied at a temperature of 400°C to determine the flow rate. **Fig. 2** shows the pictorial views of MFI testing. Three repetitions were made to calculate the MFI, which comes out to be 3.01 g/10 min. The evaluation of MFI as basic rheological property was required to ascertain the flow of

Fig. 3 ASTM D638 Type V specimen (All dimensions in mm).

Fig. 4 Specimens printed by fused deposition modeling.

Table 1 Effect of infill percentage on peak strength

Sample no.	Infill density (percentage)	Peak strength (MPa)
1	60	51.3
2	80	68.8
3	100	70.2

extrudate from commercial FDM setup. Since most of commercial FDM setups are designed for thermoplastic with MFI of 2–2.5 g/10 min and work in the range of 250–300°C, to run the PEEK feed stock filament, the print head temperature needs to be increased.

After establishing MFI for the selected PEEK granules, feed stock filament was prepared on a single screw extruder. The in-house prepared feed stock filament was fed to FDM setup and functional prototypes were prepared at 50 mm/s printing speed, with 04 number of perimeter layers, print bed temperature 110°C, and travel speed of 120 mm/s with rectilinear fill pattern. The functional prototypes were prepared as per ASTM D638 type V standard (see Fig. 3).

Tensile Testing

Fig. 4 shows 3D printed tensile samples as per ASTM D638 Type V.

For understanding the effect of infill density expressed as infill percentage three specimens were printed with different infill density and subjected to tensile testing for evaluation of peak strength. Table 1 shows effect of infill percentage on peak strength.

As observed from Table 1, as the infill percentage is increased, tensile strength is improved. The typical values of tensile strength for PEEK in literature for injection molded samples have been found to be about 90 MPa. But here, for 3D printed samples

Fig. 5 Fractured tensile test specimen.

Fig. 6 Stress–strain diagram for 3D printed samples.

Table 2 Observations for Shore D hardness

Sample no.	Shore D hardness
1	70.5
2	74.0
3	80.0

Table 3 Observations for peak strength and Shore D hardness

S. no.	Peak strength (MPa)	Shore D hardness
1	70.26	80.26
2	70.27	80.27
3	70.28	80.28
4	70.24	80.24
5	70.24	80.24
6	70.23	80.23

observed value of peak strength has shown a dip, which may be due to porosity/air gap between subsequent layers during the printing process. **Figs. 5** and **6** respectively show the sample after tensile testing and stress–strain diagram for printed samples as per **Table 1**.

Hardness Test

The 3D printed specimens as per **Table 1** were tested for hardness on Shore D Durometer (see **Table 2**).

As observed from **Table 2** maximum hardness was observed for sample 3 with 100% infill density, which is obvious as more density will result in more rigidly stacked layers.

Based upon observations in **Tables 1** and **2** sample no. 3 was considered better. Now to understand whether the process is under statistical control, 06 PEEK samples were printed with 100% infill density, 50 mm/s printing speed, with 04 number of

Table 4 Observations for peak strength for 06 repetitions

Run no.	Observations for peak strength (MPa)	Average	Over average/below average (OA/BA) w.r.t. mean	Above (A) or below (B) the previous reading

Average	70.25		E(run) = Change from OA to BA = 1	Change from A to B = 1

Table 5 Observations for Shore D hardness for 06 repetitions

Run no.	Observation	Average	Over average/below average (OA/BA) w.r.t. mean	Above (A) or below (B) the previous reading
1	80.24	80.25	BA	–
2	80.24	80.25	BA	–
3	80.23	80.25	BA	B
4	80.26	80.25	OA	A
5	80.27	80.25	OA	A
6	80.28	80.25	OA	A
Average	80.25		E(run) = Change from BA to OA = 1	Change from B to A = 1

perimeter layers, print bed temperature 110°C, and travel speed of 120 mm/s with rectilinear fill pattern. The observations for peak strength and Shore D hardness is given in **Table 3**.

Based upon **Table 3**, **Table 4** and **Table 5** respectively show statistical analysis for 06 repeated observations with respect to (w.r.t) mean value.

In the present study, the sample size of the observations as well as the number of samples was small, so the X-bar and R-chart could not been drawn.

Calculating standard normal deviate (Z) for OA and BA:

Expected number of above and below runs, $E(\text{run}) = 1 + N/2 = 4$

And standard deviation, $\sigma_{AB} = \sqrt{(N - 1)/4} = 1.118$

So, $Z_{OABA} = (1 - E(\text{run})_{OABA})/\sigma_{OABA} = -2.68$

$|Z_{OABA}| = 2.68$

Further, calculating 'Z' for A and B:

Expected number of up and down runs, $E(\text{run}) = (-1 + 2N)/3 = 3.666$

$\Sigma_{AB} = \sqrt{(-29 + 16N)/90} = 0.8628$

And, $Z_{AB} = (-E(\text{run})_{AB} + 1)/\sigma_{AB}$
 $= -3.091$

$|Z_{AB}| = 3.091$

For calculating Z critical, [NORMSINV (- $\alpha/2$)+1] formula of Microsoft Excel has been used by assuming a marginal error (α) as 0.05.

$$\text{So, } Z_{\text{critical}} = 1.959963$$

It has been found that $|Z_{OABA}|$ and $|Z_{AB}|$ both have greater value than Z_{critical} , which highlights the presence of random-free pattern. In the present work, the cumulative probability (P_i) plot was drawn with the help of following rule:

$$\text{Cumulative Probability, } P_i = (-0.5 + \text{Sr.No.})/N$$

Where "N" is the total number of observations and "Sr. No." is serial number of observation in ascending order.

Standard normal deviate (Z):

$$Z = (-\mu + X_i)/\sigma$$

As "Z" follows normal distribution with (mean (μ) = 0 and standard deviation (σ) = 1) hence the equation obtained presently follows normal probability curve. For the calculation of "Z," [NORMINV(P_i)] formula of Microsoft Excel has been used. The observed values, P_i , and Z (in ascending order) are given in **Table 6**. Based upon **Table 6**, **Figs. 7** and **8** shows the best fitted curve for normal distribution of data (peak strength and shore D hardness).

Table 6 Observed value, P_i and Z

<i>S. no.</i>	<i>Observed value (peak strength)</i>	<i>Observed value (Shore D hardness)</i>	P_i	Z
1	70.23	80.23	0.083	−1.38299
2	70.24	80.24	0.25	−0.67449
3	70.24	80.24	0.416	−0.21043
4	70.26	80.26	0.583	0.21043
5	70.27	80.27	0.75	0.67449
6	70.28	80.28	0.916	1.38299

**Fig. 7** Best fitted curve for normally distributed data (peak strength).**Fig. 8** Best fitted curve for normally distributed data (shore D harness).

From the above statistical tests, it has been observed that a nonrandom pattern has been followed by the aforesaid data. Further the data follows normal probability curve as desired hence there is a high probability for this process to be statistically controlled in case of batch and medium production runs.

Differential Scanning Calorimetry

Finally sample 3 (as per Table 1), with better mechanical strength and hardness, was subjected to differential scanning calorimetry (DSC) analysis for thermal stability. Exothermic and endothermic heating/cooling rate was 10°C/min with N₂ gas supply of 50 ml/min. Fig. 9 shows the DSC graph for sample no. 3. As observed from Fig. 9, in two repetitive heating/cooling cycles the melting peak was observed at around 338.04–339.71°C and solidification peak 277.57–281.08°C. Similarly the change in normalized heat input was insignificant (i.e., from 24.88 J/g to 24.77 J/g). This justifies the thermal stability of the selected 3D printed samples for use as biomedical scaffolds/implants.

Fig. 9 Differential scanning calorimetry of 3D printed polyether-ether-ketone sample no. 3.

3D Printing of PEEK for Sustainability

The PEEK based composite materials are a novel invention and the application of such materials for handling nuclear waste is in their beginning phase. Some studies have been reported for use of PEEK polymers for suitable resistance to radiations (Kulshreshtha and Vasile, 2002). The resistance to radiations and high temperatures still precludes this polymer based composite from uses inside the core of fission or fusion reactors. But this material has some applications within the nuclear industry and space industry, at least where the radiation fields are moderate or low. The use of 3D printed PEEK based containers for radioactive waste storage applications needs to be explored. Whatever is the type of radiation (charged or neutral particle, or electromagnetic radiation of enough energy) its effect always results in excitation and ionization of the polymer chain. Polymers are usually electrical insulators; if they are subjected to high dose-rate irradiation, the number of free electrons may reduce significantly their resistivity, but this is only a transient effect. If charged particles are used, electric charges may accumulate in organic insulators and seismic loads, making this material very useful for the present day nuclear waste disposal chamber (Tavlet and Ilie, 1999). The 3D printed PEEK based waste container can be crucial components in conducting a defensible safety assessment.

Summary

The 3D printing of PEEK based functional prototypes was successfully performed in the present case study with small alteration in print head hardware of a commercial FDM setup. The functional prototypes prepared were subjected to mechanical, rheological, and thermal stability investigations. The result of this study suggests that 3D printed PEEK functional prototypes are thermal stable. The MFI 3.01 g/10 min is acceptable for successful printing on any commercial FDM printer with small iteration in print head. Finally peak strength of 70.2 MPa and surface hardness of 80 Shore D was obtained for 3D printed functional prototypes, which are acceptable for biomedical scaffolds/implants. The results of the

study suggest that data for peak strength and shore D hardness follows normal probability curve, hence there is high probability for this process to be statistically controlled.

Recyclability of Natural Fiber-Filled Thermoplastic Composites

Riza Wirawan, State University of Jakarta, Jakarta, Indonesia

© 2020 Elsevier Inc. All rights reserved.

Introduction

The use of natural fiber composites has been becoming popular since the end of the 20th century. One of the main reasons is the environmental awareness. Besides, many researchers reported the advantages of the natural fiber composites as compared to the conventional composites in some areas, including acceptable specific properties, biodegradability, energy recovery, CO₂ balance, and recyclability properties. Those advantages lead to the growing demand in a lot of industries, including automotive, building, and construction (Faruk *et al.*, 2014).

Many authors mentioned the environmental issues to describe the advantages of natural fiber composites in comparison with conventional composites, such as glass and carbon fiber reinforced polymers (GFRP and CFRP). It is related to the properties of a natural fiber, such as biodegradable and CO₂ balance (Bledzki and Gassan, 1999; Braga *et al.*, 2017; Maciel *et al.*, 2018; Monteiro *et al.*, 2009; Shahinur and Hasan, 2019). However, the environmentally friendliness of a natural fiber composite becomes questionable when the natural fiber is incorporated in a synthetic polymeric matrix due to ecological threat from the polymer. It is well known that the synthetic polymers are resistant to biodegradation. The volume of polymeric waste has been accumulated in the environment and creating a serious problem (Fakhrul and Islam, 2013). Hence, recyclability of the composites must be considered.

Another question is then raised when a natural fiber is incorporating into a thermoplastic polymer. In theory, a close-loop recycle of most thermoplastics is possible when it is not contaminated with other materials (Hopewell *et al.*, 2009). The possibility is then questioned when the thermoplastic is “contaminated” with a natural fiber. In this chapter, reports related to the recyclability of natural fiber-filled thermoplastic composites and its recycling processes are reviewed. For better understanding, the discussion is begun with the waste management strategies and recycling processes of the composites in general, followed by the recycling process of thermoplastic composites and the natural fiber-filled thermoplastic composites.

Waste Management Strategies

There are five broad waste management strategies, also called as waste hierarchy, namely prevention, preparing for reuse, recycling, recovery, and disposal (Rybicka *et al.*, 2016). Table 1 shows the stages of management hierarchy, starting from the most desirable one (Defra, 2011).

Prevention or waste minimization offers the highest economic and environmental benefit by increasing the efficiency of the material usage and minimizing the waste at the first place. One of the efforts is developing a manufacturing process which results in minimizing the production waste (Conroy *et al.*, 2006). Preparing for re-use, including refurbishing and repairing parts, is also a desirable option. However, not all the products can be reused. Hence, in regards with composite materials, most of the researcher focus on the recycling technologies to convert the unused materials into another valuable products (Correia *et al.*, 2011; Rybicka *et al.*, 2016). Some efforts fall into recycling stage in the waste management hierarchy but some others fall into reuse and energy recovery (Rybicka *et al.*, 2016). Hence, practically, recycling process of a composite covers three stages in the waste management hierarchy, including preparing for re-use, recycling, and other recovery.

Recycling Processes of Composites

Developments in composite recycling is highly related with developments in thermoset composites recycling. However, some of them can be modified to recycle thermoplastic composites. Research in this area is divided into three eras (Overcash *et al.*, 2017). The

Table 1 The waste management hierarchy

Stages	Includes
Prevention	Waste minimization, using minimum volume of material in design and manufacturing, longer product life-time, reuse, avoiding the using of hazardous materials
Preparing for re-use	Refurbishing and repairing parts
Recycling	Converting waste into a new product
Other recovery	Any activities recovering energy, backfilling operations
Disposal	Landfilling and combustion without energy recovery

Note: Defra, 2011. Government Review of Waste Policy in England 2011. London: Department for Environment, Food and Rural Affairs. Rybicka, J., Tiwari, A., Leeke, G.A., 2016. Technology readiness level assessment of composites recycling technologies, J. Clean. Prod. 112, 1001–1012. doi:10.1016/j.jclepro.2015.08.104.

first era is in the years of 1980–2006, when the efforts focus on recovering fibers and resin from composite. The second era is in the years of 2009–2012, when researchers find a way to incorporate recovered fibers into a new thermoset resin, following by the third era (2012–2016) when the development turned into retaining the original fiber/resin properties and make a new composite.

Recycling processes are carried out in various techniques. They are divided into at least three processing, namely mechanical, thermal, and chemical processing (Asmatulu *et al.*, 2014; Feraboli *et al.*, 2012). In mechanical processing, a composite part is crushed through a series of mills producing various particle sizes ranging from 5 μm to 10 mm. Product of the recycle process, named as recyclate, is still a mixture of the fiber and matrix. The recyclates can be used as a filler in another composite, which is not a structural composite, as a replacement of calcium carbonate. This filler may reduce the density of the replaced materials. Moreover, there is a potential use of fibrous recyclates as reinforcement (Asmatulu *et al.*, 2014; Pickering, 2006), despite higher energy is needed to improve the quality of a recyclate (Shuaib and Mativenga, 2016).

Thermal processing is commonly used to separate fibers from a thermoset matrix. It requires external heating to transform the phase of the matrix into liquid or gas and hence separating the fibers from the polymer (Asmatulu *et al.*, 2014; Conroy *et al.*, 2006; Pickering, 2006). Due to the difference in decomposition temperature among elements in a composite, the thermal process is also used for separating the components of a composite. As an example, when the temperature of glass fiber reinforced composite is increased, the matrix will firstly decompose and leave the glass fibers and other inorganic parts as a residue, due to higher decomposition temperature. The thermal processing includes combustion, pyrolysis, and fluidized-bed processes (Asmatulu *et al.*, 2014; Oliveux *et al.*, 2015).

Combustion process of thermosetting polymer matrix composite produces a source of heat which can be converted into various energy, including electricity and mechanical energy, due to a high calorific value of the thermosetting polymer (Asmatulu *et al.*, 2014). Hence, when a thermosetting resin is burned, the composite converts into energy and a residue contained fibers and other inorganic materials. The residue can then be used as a reinforcement or filler in a new composite as well as other purposes. The burning process may also be carried out in a cement kiln. In this process, the heat released from the matrix is used for the cement production. At the same time, the glass silica is used as a filler in the cement. As a result, it reduces the overall cost (Asmatulu *et al.*, 2014; Pickering, 2006).

Fluidized-bed is a bed of silica sand which is fluidized with a hot air stream. It heats up a composite rapidly and volatilized the organic part of the composite, leaving the inorganic parts as a solid particulate. The process is then completed with Pickering's process to separate fibers from fillers. Furthermore, the organic part or the resin is degraded by transferring it to a secondary combustion chamber at a temperature of about 1000°C. The degradation produces a clean flue gas. Hence, the process produces fibers and fillers, that can be reused in a new composite manufacturing or other applications, and a clean flue gas that can be used as a source of heat or energy (Asmatulu *et al.*, 2014; Oliveux *et al.*, 2015; Pickering, 2006; Pickering *et al.*, 2000; Zheng *et al.*, 2009).

Pyrolysis is a thermal decomposition of materials at a high temperature in the absence of oxygen. This process at 300–800°C allows the recovery of long fibers under the controlled temperature and time (Blazsó, 2009; Yang *et al.*, 2012). Mainly, this process aims to obtain the recycled fiber in a good condition to be reused in other applications (Yang *et al.*, 2012). Since the beginning of 21st century, microwave-assisted pyrolysis has also been developed. It offers very fast thermal transfer by heating the materials in its core (Oliveux *et al.*, 2015).

Chemical recycling process is an effort to dissolve the solid composite into different liquid products (Asmatulu *et al.*, 2014). The process is often called solvolysis and classified based on the solvent used. The classification namely hydrolysis, glycolysis, and acid digestion, which are carried in the solution of water, glycols, and acid, respectively (Yang *et al.*, 2012). There are many researchers reported the experiments on chemical recycling process with various solvents under various temperature and pressure (Bai *et al.*, 2010; Liu *et al.*, 2012; Piñero-Hernanz *et al.*, 2008). However, only few of them successfully reached the industrial-scale (Oliveux *et al.*, 2015).

Recycling Processes of Thermoplastic Composites

Recycling method of thermoplastic composites includes mechanical, thermal and chemical recycling (Oliveux *et al.*, 2015; Yang *et al.*, 2012). Among the processes, remelting and remolding process, or often called as direct re-processing, is more studied for scrap processing. This process offers no separation process of fiber and matrix but results (Yang *et al.*, 2012).

Schinner *et al.* (1996) studied two approaches in recycling carbon-fiber-reinforced thermoplastic composites. The first approach is grinding the composites and using the grinding fractions in injection or press molding compounds. The other approach is reforming process without grinding. Both approaches show minimum changes in the material properties, indicating a good recyclability of the thermoplastic composite. Moreover, Steenkamer and Sullivan (1998) reported a similar result for a cyclic thermoplastic composite material, which was recycled by grinding, followed by compounding, and injection molding. Physical and thermal properties of the recycled cyclic thermoplastic materials are comparable to those of a commercially available thermoplastic composite, with an exception in the elongation.

Li and Englund (2011) reported a close-loop recycling of the thermoplastic composite is possible under a proper process parameter. The particle size of mechanical refined scraps affects the mechanical properties of a recycled thermoplastic composites. The finer scraps resulted in the higher mechanical properties. Furthermore, a recent study on the recycling of thermoplastic reported that a chemical process, namely dissolution, allows a recovery of both fiber and matrix while maintaining their stiffness and strength (Cousins *et al.*, 2019; Liu *et al.*, 2018).

Recycling Processes of Natural Fiber-Filled Thermoplastic Composites

Despite the increase in research on natural fiber-filled thermoplastic composites, only few of them focused on its recycling and recyclability. Morán *et al.* (2007) extruded a flax fibers-reinforced polypropylene (PP) at multiply cycles and reported that the

process resulted in thermo-mechanical degradation. The recycled product performed higher modulus but lower in strength. The product, however, can be used for industrial application when a compatibilizer is incorporated.

Meanwhile, Sanetuntikul (2008) reported that the mixture of wood plastic composite (WPC) scrap and WPC fresh-feed at a ratio of 30:70 can be recycled up to five cycles without significant effect to the thermal and mechanical properties of WPC.

Furthermore, Twite-kabamba *et al.* (2010) recycled a birch fiber/low density polyethylene up to ten cycles of extrusion. It was found that the extrusion process increased the polymer crystallinity and decreased the zero-shear viscosity. At the same time, the fiber length and diameter also decreased.

Recently, recyclability studies were also carried out on oak wood flour (WF) filled HDPE (Bhattacharjee and Bajwa, 2018) and sugarcane bagasse (SB) filled PP (Lila *et al.*, 2018). After recycling process, the strength, stiffness, and crystallinity of WF/HDPE decreased while the strain and thermal stability increased. Meanwhile, the tensile properties, hardness, and crystallinity of SB/PP increased after recycling without significant.

The various results reported in regard with the recycling of natural fiber-filled composites indicating that there are many factors affects to the recyclability of the composite. The different properties of the recyclates are obtained in consequence of the raw material, processing, and environmental effects (Winandy *et al.*, 2004).

Summary

In general, among so many composite recycling processes, the most feasible recycling process for the thermoplastic composites is to reproduce with or without scrapping. A close-loop recycle of natural fiber-filled thermoplastics is possible due to the properties of thermoplastic. The close-loop recycling of thermoplastic has been widely practiced in industries. An addition of the natural fiber, however, make it more complicated. The properties of the fiber, including physical and chemical properties, play an important role in recyclability of the composite. The most issue discussed in many reports is the fiber degradation during processing, due to thermal and shear stress. In the end, there are a huge area of research need to be explored in regards with the recyclability of natural fiber-filled thermoplastic composites. The development continues.

Renewability of Polymer-Based Thin Films for Packaging

Adriane G Ludwick and Heshmat A Aglan, Tuskegee University, Tuskegee, AL, United States

© 2020 Elsevier Inc. All rights reserved.

Overview

A brief summary of the history of food packaging (Risch, 2009) shows that the development of materials has impacted the food industry. Before 7000 BCE, ceramics and glass were used for packaging. In the 1900s, the catalytic effect of the military's need for nonperishable packaged food led to the use of synthetic polymers for packaging. Throughout that entire period to now, the ingenuity of humans has made an impact on the environment. Risch (2009) makes a brief note on efforts towards sustainability in the summary of her paper. Certainly not being harmful to the environment or depleting natural resources (i.e., sustainability) would be desirable. The reality is that nearly all of the thin films currently used for packaging comes from a non-renewable resource, fossil fuels (van den Oever *et al.*, 2017; Hodges, 2018).

Hodges (2018) describes the current global status of the cost of crude oil and the production of polymers from crude oil. He notes that in 2016, 46% of poly(ethylene) (linear low density poly(ethylene) (LLDPE), low density poly(ethylene) (LDPE), and high density poly(ethylene) (HDPE)) was used for flexible packaging; 22% of poly(propylene) (PP) was used for flexible packaging. This represents nearly 58 million tons of these materials. Hodges discusses the uncertainties in the global market with respect to crude oil and polymer production from the crude oil. Significantly, he describes the change to manufacturing sustainable materials; his current prediction is that sustainable materials will be manufactured from non-renewable polymer-based materials. He notes that the cost of manufacturing packaging from renewable resources is not competitive with the production of packaging from recycled non-renewable polymer-based materials.

Pollution caused by non-sustainable plastics is a major concern (Kershaw, 2015; WWF; North and Halden, 2013; Bradley, 2017) that has generated a variety of views. The initial concern about the larger, visible pieces of non-sustainable plastics has evolved to a concern about microplastics (Rochman, 2018). Additionally, the focus of research on microplastics has moved from materials in the oceans to materials in fresh water, soils, and the air. In other words, the concern has literally become global (Rochman, 2018). A multi-year study of plastic debris in the eastern Pacific Ocean, combined with data from other sources, gave a clear picture of the concentration of the debris in a particular region of the ocean (Law *et al.*, 2014). Over an 11-year period (2001–2012), annual cruises occurred where samples were collected systematically from the eastern part of the Pacific Ocean. An estimate of more than 21×10^3 tons of floating microplastic was derived from this study. The observed concentration of the plastic in the northeast region of the Pacific Ocean was consistent with models based on the currents of the ocean. Law *et al.* (2014) are careful to note the challenge of obtaining useful data on the trends in accumulation of plastics in the ocean. For example, they attempt to include the effect of wind data into the conclusions from their data set but note that this wind data is not always available. Regardless, their results clearly provide a basis for understanding the magnitude of the accumulation of plastic waste in the ocean.

Data on the transport of plastics from rivers to oceans (Schmidt *et al.*, 2017) was interpreted to estimate that between 0.4 and 4×10^6 tons per year are so transported. As expected, calculations on the concentration of plastic waste in rivers relative to the concentration of plastic waste in oceans showed that the river concentration is greater than the ocean concentration by a factor of 40–50 times. The information for the this paper (Schmidt *et al.*, 2017) paper came from ten peer-reviewed publications and three non-peer-reviewed publications. These overviews on ocean data (Law *et al.*, 2014) and rivers (Schmidt *et al.*, 2017) are valuable resources on this environmental concern. Very recently, the American Chemistry Council reported actions taken at the June 2018 G7 meeting in Canada indicating the global concern for this issue (Killenger, 2018). Obviously, removing the non-renewable plastic waste from our oceans is one issue; developing a renewable resource solution to packaging is equally important.

Renewability

Renewability refers to materials that can be replaced by new growth. In that sense, natural polymers such as polysaccharides are renewable. They are obtained from various natural sources. Unfortunately, without modification, polysaccharides cannot be a replacement for polymers from fossil fuels that are used to produce thin films that are used for packaging. The permeabilities to oxygen, carbon dioxide, and water vapor of low density poly(ethylene) (LDPE), as well as the mechanical properties of films prepared from LDPE, are superior to the properties of polymeric thin films prepared from renewable materials. A thin film made from starch, for example, will have a high water vapor sensitivity and will also have poor mechanical properties. These differences will be presented in this article.

Considerable research has been published on polymeric thin films from renewable resources. A number of recent reviews provide an indication of the magnitude and importance of the work on this subject (van den Oever *et al.*, 2017; Cazon *et al.*, 2017; Wang *et al.*, 2018b; Madhumitha *et al.*, 2018; Schneiderman and Hillmyer, 2017; Hu, 2014; Nagarajan *et al.*, 2016; Shah *et al.*, 2015). Although business projections predict an increase in the production of polymeric thin films from renewable resources (van den Oever *et al.*, 2017), the contribution of these films to the total production is predicted to remain small in the near future.

Competing strongly with the development of polymeric thin films from renewable resources is the development of thin films through recycling of fossil fuel-based polymers (Hodges, 2018; Neufeld *et al.*, 2016). Improvement in both cost and properties for renewable resource polymeric thin films is necessary if these films are to be competitive with polymeric thin films obtained from non-renewable fossil fuels. However, the cost factor will not be the focus of this article. Instead the focus will be on the properties of the polymeric thin films. These properties will be presented for neat renewable materials and for modified renewable materials. These properties for the renewable materials will be compared to those of commonly used packaging thin films synthesized from fossil fuels. The physical, thermal, and mechanical properties will be discussed. Just as the properties of synthetic polymers can be modified by mode of synthesis, modest changes in functionality, addition of nanomaterials, various degrees of crosslinking, etc., so can natural polymers such as polysaccharides be modified in order to improve properties for particular applications. It is from this point of view that this article will be presented.

This article is not intended to be a complete review; it is intended to be a presentation of recent work done in the area of improving the properties of polymeric thin films from renewable resources for the application of packaging. While it is hoped that there will be a “magic bullet”, or at least hint of a pathway towards potential “magic bullets”, that will inspire production of thin films for packaging that come from renewable resources, it is also hoped that the readers of this article will be inspired to continue the effort to develop polymeric thin films from renewable sources.

Non-Modified Biopolymer Films

This section will discuss films from renewable sources that have been processed but are essentially the renewable material. Later in this article, modified biopolymer films will be discussed.

Polysaccharides

Polysaccharides include starch, cellulose, chitin, and hemicellulose. Considerable work has been done historically on the modification of these materials in order to improve their properties for particular applications while still retaining their ability to biodegrade without environmental damage (Narayan, 1994; Roman, 2010; Halley *et al.*, 2008; Hansen and Plackett, 2008). More recently, this topic has been reviewed towards the goal of providing a summary of what is currently being done, as well as the strengths and weaknesses of the current research (Wang *et al.*, 2018b; Rajinipriya *et al.*, 2018).

Starch

There are various types of starches from natural sources (potato, wheat, rice, corn, etc.); the differences depend largely on the amylose and amylopectin content of the starch. Films prepared from starch generally have low oxygen permeability and low water vapor permeability (Liu, 2008). These barrier properties, of course, makes starch films good candidates to compete with films from fossil fuels. However, starch films are brittle and can have tensile strengths as low as 1 MPa (Liu, 2008). Interestingly, the incorporation of plasticizers into the starch base gives films not only with improved mechanical properties but also with improved barrier properties (Liu, 2008; Combrzynski *et al.*, 2013; Shah *et al.*, 2015). Other modifications of starch to give that result in improved films for packaging will be discussed in the section of this article on modified biomaterials. Some properties of starch films are shown in Table 1.

Cellulose

A review of cellulose nanomaterials (CNMs) (Wang *et al.*, 2018b) provides detailed information on cellulose films, CNM coatings, and CNM nanocomposites. The information on films will be discussed in this section. The section on modified biopolymers will discuss the coatings and nanocomposites using CNMs. The intent of the review (Wang *et al.*, 2018b) is to provide a common connection among the various reports on CNMs, particularly the CNMs used for food packaging. The authors note the importance and difficulty of knowing where a particular CNM falls in the spectrum of possible dimensions. The review provides specific dimensions for cellulose microfibrils (CMFs), cellulose nanofibrils (CNFs), and cellulose nanocrystals (CNCs) while noting that many reports do not use these designations; hence production methods were used to distinguish CNMs.

Moisture absorption by CNMs is a complex phenomenon; two major considerations are morphology of the CNM and surface functionality. Water vapor permeability measurements allow a ranking of films with respect to this quality. An understanding of this ranking is more challenging. Even so, the best results located by Wang *et al.* (2018b) for this measurement, based on various sources using similar procedures, are shown in Table 1. Similarly, oxygen permeability is an important measurement for the comparison of various films that are used or have the potential for being used as a packaging material (Table 1). The CNM with high ranking values for both water and oxygen permeability is indicated. While there were other CNMs that performed well in one or the other or both categories, the range of values for water permeability and oxygen permeability were from 10.63×10^{-15} to 321.9×10^{-15} and 2.14×10^{-21} to 184.4×10^{-21} kg m/m² s Pa, respectively. For comparison, values for films derived from common petrochemicals are also given. For these non-renewable films, polyvinylidene chloride (PVdC) gave the best values in both water and oxygen permeability.

Table 1 Properties of non-modified biopolymer films

Film	Permeability ($\text{kg mm}^{-2} \text{s}^{-1} \text{Pa}^{-1}$)			Mechanical properties			Reference
	Oxygen	Carbon dioxide	Water vapor	Tensile strength, MPa	Elongation at break, %	Modulus, MPa	
CNM: CMFs, refined and ground	3.7×10^{-21} to 4.6×10^{-21}		10.6×10^{-15}				Wang <i>et al.</i> (2018b)
CNFs, carboxylated, Ca^{+2}	0.33×10^{-21}						Wang <i>et al.</i> (2018b)

^aData is for PLAs that are 94% and 98% L-lactide, respectively.

Fig. 1 Chemical conversion of chitin to chitosan.

Surface functionality change as subtle as the counter ion for a carboxylate of a CNM was reported to play an important role in the oxygen permeability ([Table 1](#)). The aluminum and calcium cations gave the best results for this parameter. The authors ([Wang et al., 2018b](#)) do not give the water permeability for these salts, although they did note that moisture increases their oxygen permeability values.

Efforts to produce a soluble cellulose system have been considerable ([Xu et al., 2018](#)). These authors have synthesized and analyzed an ionic liquid/cellulose system that dissolves cellulose at 25°C and from which cellulose can be easily regenerated. Success in this arena would be invaluable in the development of thin films for packaging from abundantly available cellulose.

Chitin/chitosan

After cellulose, chitin is the second most available biopolymer. Since chitin is a very insoluble material, it is generally transformed to its more soluble derivative chitosan. Chitosan is prepared by the deacetylation of chitin. This can be done by various versions of chemical syntheses ([Fig. 1](#)) ([Hadi, 2013](#); [Long, 2013](#); [de Queiroz Antonino et al., 2017](#)). A variety of other approaches is discussed by [Liu et al. \(2017\)](#); these include the use of (1) an enzymatic catalyst rather than a highly concentrated aqueous sodium hydroxide solution, (2) microwave radiation to provide the energy source for the reaction in aqueous sodium hydroxide, (3) autoclaving and γ irradiation of the chitin/aqueous sodium hydroxide solution, and (4) ionic liquids and heat as the medium for the deacetylation. These methods are critiqued by [Liu et al. \(2017\)](#) as related to cost and/or environmental factors. These authors present an approach using glycerol and somewhat lower concentrations of sodium hydroxide to react with the insoluble chitin. Additionally, they present a method to recover most of the glycerol/sodium hydroxide reaction medium for reuse.

Pure chitosan is used as a packaging film. A review specifically devoted to pure chitosan and its derivatives and their potential for food packaging applications ([Wang et al., 2018a](#)) provides a summary of current efforts in this area. As a polycation, pure chitosan is noted for its antimicrobial activity. Its oxygen barrier properties and its mechanical properties are good ([Wang et al., 2018b](#)), although they do not match the films from fossil fuels that are currently in use. The water barrier properties of pure chitosan, as expected, are poor. There are simply too many sites for hydrogen bonding of water and chitosan. Some of the properties of pure chitosan are given in [Table 1](#). From this data, it is evident that pure chitosan will not become competitive as a thin film for food packaging. However, since chitin is such a dominant natural resource and since the production of chitosan from chitin is so well established, it is clear that there should be considerable effort towards the production of chitosan derivatives for this application. The most current work in this area will be discussed later in the article.

[McDonnell et al. \(2016\)](#) modeled a chitosan/chitin system. The system had fifteen monomer unit chains; five were chitin and ten were chitosan, representing 66% deacetylation. Twenty percent of the chitosan molecules were protonated. The relative humidity range for the molecular dynamics study was 15%–95%. Molecular oxygen was introduced so as to give random trajectories. This computational effort is quite detailed both in terms of the work itself and in terms of analyzing other literature efforts related to their work. The oxygen permeability predicted from the first level of calculations showed oxygen to be more permeable at low relative humidity; this was the opposite to experimentally reported results. Adjustment of their calculations gave results with the correct trend but still not in agreement with experimental values at low relative humidity. Based on the literature and on their work, the authors infer that the presence of isolated aqueous domains in the chitin/chitosan polymer chain would lower oxygen permeability. Future ab initio calculations are suggested by the authors to provide a more accurate model to predict oxygen permeability for the chitin/chitosan system.

Hemicellulose

The composition of hemicellulose varies with feedstock ([Hansen and Plackett, 2008](#)). This is a significant difference in comparison with polymers made from monomers derived from fossil fuel feedstock. While the fossil fuel feedstocks vary, refining produces very specific monomers that are used to prepare specific polymers.

The oxygen permeability and mechanical properties of hemicellulose thin films make hemicellulose a very good candidate for packaging ([Table 1](#)) ([da Cunha Gonçalves, 2011](#)). However, the biggest challenge for the use of hemicellulose as a thin film for packaging is the moisture vapor permeability of its thin film. There has been success in the chemical modification of hemicellulose thin films. Acetylation using acetic anhydride ([Fig. 2](#)) is a classic example of a modification that decreases moisture permeability. Somewhat more recently ([Hartman, 2006](#)), benzylation was shown to significantly decrease moisture vapor permeability while still maintaining acceptable oxygen permeability and mechanical properties. More recent modifications of hemicellulose films are discussed in the modified biomaterials section.

Fig. 2 Acetylation of hemicellulose.

Table 2 Comparison of glass transition, melting point, and percent crystallinity for PLA, PS, and PET

Polymer/property	PLA ^a	PS	PET
T _g , °C	66.1; 71.4	100	80
T _m , °C	140.8; 163.4	NA	245
Crystallinity, %	25; 40	NA	38

^aData is for PLAs that are 94% and 98% L-lactide, respectively.

Films From Biomonomers

Poly(lactic acid) (PLA)

The potential of poly(lactic acid) (PLA, the polymer from lactic acid (2-hydroxypropanoic acid)) as a renewable material is well established (Auras *et al.*, 2004). The biomass corn can be converted to lactic acid, which is then converted to PLA. Molecular weights of more than 100,000 daltons have been produced from lactic acid. The chiral center of lactic acid provides the basis for variations in the PLAs that can be synthesized. High molecular weight and amorphous PLA has a T_g of 58°C and decomposes between 215 and 285°C. Semi-crystalline PLA has a T_g between 58 and 70°C, a melting point range from 130 and 207°C, and decomposes between 215 and 285°C.

Auras *et al.* (2004) draw a comparison among PLA, poly(styrene) (PS), and poly(ethylene terephthalate) (PET) (Table 2). This comparison certainly shows that PLA is comparable to these synthetic polymers. They also note that the surface tension values for PLA are comparable to those of PS and PET; these values are somewhat higher than those for poly(ethylene) (PE) and poly(propylene) (PP). While moisture absorption by PLA is higher than that for PS and PET, this absorption has no significant effect on the T_g for PLA.

The limitations of “pure” PLA as a packaging material become obvious when processing is considered. There is only a 12°C window for processing in order to avoid degradation of the polymer (Auras *et al.*, 2004). The thermal stability of PLA is similar to that of poly(vinyl chloride) (PVC); PLA is less thermally stable than PS, PET, PE, and PP. The mechanical properties of PLA are similar to those of PS; the mechanical properties of PLA and PET are less similar. A useful property for PLA is its insolubility in water. In comparison to PS and PET, PLA has comparable properties as a barrier to carbon dioxide (Table 1); the oxygen permeabilities for PS and PET are similar to that for PLA; additionally, the water vapor permeability coefficient for PLA is similar to those for PS and PET (Table 1).

In addition to PLA originating from a renewable resource, PLA is degradable. The initial degradation occurs by hydrolysis of the ester linkage of the polymer. Finally, the lower molecular weight products from the hydrolysis are degraded further by microorganisms. Originating from a renewable resource and then degrading in the environment are clear advantages for the use of PLA in packaging. Recent efforts to modify PLA by creating blends or copolymers, or by the addition of materials to create composites is the current focus and will be discussed in another section of this article.

Films From Bacterial Biosynthesis

Poly(hydroxyalkanoates) (PHA)

In order to improve the economic competitiveness of polyhydroxyalkanoates (PHAs) as packaging films, various methods to obtain PHA were compared systematically. PHA is produced naturally. The most common method to extract PHA from biomass has been dichloromethane extraction. In this work (Gutt *et al.*, 2016), seven methods to extract poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (P3HBHV) from *C. nectar* biomass were compared. The extraction methods were: (1) solvent extraction with dichloromethane; (2) polycarbonate; (3) ionic liquids; (4) enzymatic lysis; (5) sonication; (6) bead milling; and (7) use of surfactants. Also, a combination of mechanical disruption and surfactants was examined. The goal was to obtain high purity P3HBHV in high yield by a process that could be recommended for industrial scale-up. Initial experiments showed the surfactant

approach (sodium dodecyl sulfate (SDS), 6 h at 90°C) gave the highest purity P3HBHV. This approach was combined with mechanical bead milling (2 min at 500 rpm) in order to optimize the processing time and hence cost. Additionally, distilled water was used for the final purification of the P3HBHV, instead of methanol. Modeling was used to optimize the protocol for the selected surfactant/bead milling method. Considered in the modeling were the weight of the biomass, the time and pH for the bead milling, and the concentration and treatment time for the surfactant. The final protocol resulting from this approach (buffer pH 2.6, milling time of 2 min at 500 rpm, surfactant concentration of 5%, and 30 min surfactant treatment time), followed by one or two distilled water washes, gave purity (92% and 94%, respectively) and yield results for P3HBHV comparable to those obtained by the traditional dichloromethane extraction method. Characterization showed trace impurities in this new approach that were ascribed to proteins and polysaccharides from the biomass cell wall and metal from the milling beads.

Poly(3-hydroxybutyrate), the most studied of the PHAs, has properties sensitive to storage time. For example, the tensile strength of PHB stored for 30 days at 50% RH is approximately 47 MPa. After approximately 60 days under the same conditions, the tensile strength reduces to approximately 34 MPa. The slope of the stress/strain curve remains the same (Bugnicourt *et al.*, 2014). Introducing valeric acid into the structure to give P3HBHV increase the elongation to break to approximately 15%; the tensile strength and modulus are 25 MPa and 1.2 GPa (Table 1). In other words the mechanical properties of the butyric acid/valeric acid copolymer (P3HBHV) are similar to those of PHB. The implication here is that in order for PHB or copolymers of PHB to be useful in packaging applications, blends or other components will need to be incorporated into these systems. Generally this is true for PHAs.

Modifications of Biopolymer Films

Attempts have been made to modify biopolymers using nanomaterials. Dispersing these very small particles in the polymer matrix can have the effect of improving barrier properties by simply making the path through the film more tortuous. The dispersion of nanoparticles in the biopolymer matrix can also improve certain mechanical properties. Other approaches have included blends of biopolymers (with or without nanoparticles), and minimal crosslinking. The number of empirical approaches may be limitless, but those reported are generally limited by systematic rationales. The possibility of developing models for the modified biopolymer films is an approach that could streamline the development of packaging films from renewable sources. This section of the article discusses some recently reported possibilities.

Polysaccharides

Starch

Ali *et al.* (2018) examined the effect of cellulose crystals and starch crystals on the properties of corn starch films. The films were made from corn starch alone and from 2%, 5%, 7%, and 10% cellulose or starch crystals in the corn starch. There were subtle but no remarkable differences between the cellulose crystal/starch (CX/S) composite and the starch crystal/starch (SX/S) composite. Of particular note is that the crystal/starch composites improved protection against UV radiation. The tensile strength, elongations at break, and modulus were affected by the addition of the crystals (Table 3); however, the changes were relatively small. It should also be noted that all the materials used in these experiments are acceptable as food ingredients.

In order to improve the water absorption and strength properties of starch films, Aqlil *et al.* (2017) examined a biocomposite composed of a starch/lignin matrix and a graphene oxide reinforcement. The lignin was extracted from sugar cane bagasse. The graphene oxide (GO) was synthesized from natural graphite. The composite film was cast from a sonicated aqueous/glycerol solution of starch and lignin (5:1 weight ratio, respectively) to which 0.3, 0.5, and 0.7 wt% GO (based on the dry starch and lignin) were added. Control films of starch and of starch/lignin were also prepared. The designations for the starch, starch/lignin, and GO-containing starch/lignin films were ST, ST/L, and ST/L-x, where x represents the percent GO in the film.

FTIR spectra of ST, ST/L, and the ST/L-x films showed systematic shifts in the starch C-O absorptions at 1152 cm⁻¹, 1077 cm⁻¹, and 1008 cm⁻¹ to 1134 cm⁻¹, 1062 cm⁻¹, and 999 cm⁻¹ for ST/L-0.7 that were interpreted to indicate a significant interaction between starch and GO. Thermal gravimetric analysis indicated that incorporation of GO into the starch/lignin system decreased the amount of water absorbed and increased slightly the thermal stability of the system. The measured moisture uptake of the films, following a slight variation of ASTM E104, for ST, ST/L, ST/L-0.3, ST/L-0.5, and ST/L-0.7 were 12.36%, 9.2%, 5.71%, 5.16%, and 5.15%, respectively. The ST/L-0.7 film had a significantly lesser water swelling than the other films. The water vapor permeability of the starch control and the ST/L-0.3 and ST/L-0.7 films are shown in Table 3. Clearly the GO is playing a role in improving the water absorption of starch films. Additionally, Aqlil *et al.* (2017) determined that the introduction of GO into the starch/lignin system appears to promote resistance to the hydrolytic degradation of these films.

The mechanical properties of the starch control and of the ST/L-0.7 film are shown in Table 3. These properties were measured for all the films; clear trends were shown: the tensile strength regularly increased from the starch control to the ST/L-0.7 film; the elongation at break decreased from the starch control to the ST/L-0.7 film; and the modulus increased from the starch control to ST/L-0.7. The addition of GO had improved the mechanical properties of the starch film. It should be noted though, for application purposes, that the addition of lignin and of increasing amounts of GO resulted in a corresponding decrease in the transparency of the films.

Cellulose

In a study where cellulose is the reinforcement and a natural rubber is the matrix (Sun *et al.*, 2018), a composite has been prepared that is potentially useful as a packaging film. The natural rubber used as the matrix, *Eucommia ulmoides*, is predominantly

Table 3 Properties of modified biopolymer films

^aThe water vapor permeability values for 1 – ST, control; 2 – ST/L-0.3; and 3 – ST/L-0.7 represent a trend but are probably incorrect by a factor of 10^{-9} .

^bS-24 = hemicellulose obtain by 24% KOH extraction of corn cobs (not desalted); S-24 A90 30 = acetylated hemicellulose obtained from S-24, reacted at 90°C for 30 min; 30-Gly-120 = desalted hemicellulose extruded at 120°C with 30% glycerol content; 30-Gly-120-A60 = 30-Gly-120 acetylated for 60 min (at 120°C).

trans-1,4-polyisoprene. Films were prepared by casting dispersions of 2%, 4%, 6%, and 8%, w/w, nanocrystalline cellulose (NCC) in a petroleum ether solution of the natural rubber; a control film (0% NCC) was also prepared. The introduction of NCC into the natural rubber enhanced the crystallinity of the rubber, as shown by the X-ray diffraction patterns of the samples. This indicated some level of interaction between the NCC and the rubber. However, NCC had little effect on the T_g and T_m of the nanocomposites. Two percent NCC decreased the T_g from -65.9°C (control) to -66.5°C . The higher concentrations of NCC did not cause any further significant change in the T_g . The T_m for the control, 51.2°C , was decreased to 50.3°C , 50.2°C , 49.2°C , and 50.7°C for the NCC concentrations of 2%, 4%, 6%, and 8%, respectively. The contact angle decreased from 90.5° for the control to 89.8° , 87.8° , 86.7° , and 76.9° for the NCC concentrations of 2%, 4%, 6%, and 8% respectively. The water vapor permeability (Table 3) reduced from $2.14 \times 10^{-16} \text{ kg m}^2/\text{sPa}$ for the control to $1.61 \times 10^{-16} \text{ kg m}^2/\text{sPa}$ for the 4% NCC/rubber composite; however, for the 8% NCC/rubber composite, the water vapor permeability was $2.03 \times 10^{-16} \text{ kg m}^2/\text{sPa}$. In terms of water vapor permeability, the 4% NCC/rubber composite is the most promising for application as a packaging material. The mechanical properties of the control, the 4% NCC/rubber composite, and the 8% NCC/rubber composite (Table 3) also favor the 4% NCC/rubber composite. However, the T_g and T_m properties would limit its use to low temperatures.

Through the use of a polyamidoamine-epichlorohydrin (PAE) (Kymene) crosslinking agent, improved films from cellulose nanofibrils (CNF) were made (Sharma and Deng, 2016). The barrier properties and mechanical properties of the CNF films degrade in humid environments. A minimal amount of the crosslinking agent was used (one percent based on the dry weight of the CNF) in order to obtain a material that would presumably still be biodegradable. In processing the CNF film, conditions were used that not only crosslinked the CNF with the PAE, but also allowed for crosslinking of the PAE molecules with themselves (Siqueira, 2012; Sharma and Deng, 2016).

The water vapor permeability of the crosslinked CNF improved considerably in comparison with the CNF that was not crosslinked (Table 3). This result was also reflected in the contact angle measurements for these materials, 110.5° and 50.2°, respectively, for the crosslinked CNF and the uncrosslinked CNF. Mechanical testing was performed on dry and wet crosslinked and non-crosslinked CNF samples. The wet samples were soaked in water for 30 min prior to testing. For both dry samples and for the wet crosslinked sample, the tensile stress at break is distinct (Table 3). However, the wet, non-crosslinked sample shows a non-linear pattern interpreted as tearing apart of fibrils whose connectivity has been weakened by absorption of water molecules between the fibrils. From the pattern of the stress-strain curves for the four samples and from SEM images of the fracture surfaces, Sharma and Deng (2016) rationalize that the PAE crosslinking serves to initially protect the cellulose fibers from breaking; once the strain has caused breaking of the PAE connectivity, then the cellulose fibers break.

Chitin/chitosan

Yang *et al.* (2018) addressed two of the poor properties of chitosan films, their water permeability and their mechanical properties. Using 90% deacetylated chitosan and the sodium salt of phytic acid, they used two approaches to prepare thin films. In one, which they called the “stripping-film technique”, they added a solution of sodium phytate onto a solution of chitosan. A film formed at the interface of the two solutions; the film was removed and dried and the process was repeated with a fresh sodium phytate solution. The second approach was called the “casting-film technique” and involved adding successive layers of chitosan and sodium phytate solutions to give a ten-layer film. Obviously, the second approach gave a thicker film (70–130 µm) than the first approach (9–26 µm). Various properties of the two types of films were examined. The water vapor permeabilities measured for both films were much lower than those for chitosan (Table 3). The best observed mechanical properties are given in Table 3. There were variations observed related to the concentrations of the solutions. Both the water vapor permeability and mechanical properties show that these films are good candidates for food packaging films. The films are reasonably transparent and both components of the films are safe to use for this application and are renewable materials.

A combination of molecular dynamic calculations and experimental measurement of mechanical properties was performed for chitosan matrices with various degrees of deacetylation that were reinforced with functionalized carbon nanotubes (CNTs); the CNT functional groups were the amine (-NH₂) or carboxylic (-COOH) groups (Aztatzi-Pluma *et al.*, 2016). Additionally, the authors examined calculations were the amide and amine functionalities on the chitin/chitosan polymer chain was varied. The calculations indicated that the strongest interaction occurred between the 50% deacetylated chitosan and the amine functionalized CNT. The experimental measurements showed a similar result; the Young's modulus for a film prepared from 54% deacetylated chitosan reinforced with an amine functionalized multiwall CNT gave the largest Young's modulus (approximately 3225 MPa). The Young's modulus for the carboxylic functionalized multiwall CNT in the 54% deacetylated chitosan was somewhat lower (3175 MPa). However, the Young's moduli for two other deacetylated chitosans (64% and 76% deacetylated) were consistently higher for the systems reinforced with amine functionalized multiwall CNTs.

Hemicellulose

Akkus (2015) explored a number of approaches towards improving the properties of hemicellulose films for packaging. Samples of hemicellulose were obtained by extraction of corn cob using an aqueous solution of potassium hydroxide. These samples were treated variously (desalted or not desalted; desalted with glycerol added; desalted with poly(vinyl alcohol) added). The purified hemicellulose was extruded at 90°C or 120°C to give 5 mm × 0.5 mm (width × thickness) “strips”. Some of the films were heat treated and some were acetylated. The properties of the various “strips” of hemicellulose and modified hemicellulose were determined. The most promising modified hemicellulose “strips” were: (1) Acetylated hemicellulose prepared from a not desalted precursor (i.e., the hemicellulose contained potassium acetate) and (2) acetylated desalted hemicellulose where the “strips” had been processed with glycerol. The mechanical properties of both types of modified hemicellulose “strips” are shown in Table 3. For both types, their water solubilities were very significantly less than that for the unmodified hemicellulose precursors. In the experiments with blends of desalted hemicellulose and poly(vinyl alcohol) (PVA), neat or acetylated, no advantage was shown for this system with respect to decreasing the water solubility of the hemicellulose. Nevertheless, Akkus' work (Akkus, 2015) provides a basis for the use of hemicellulose as a thin film packaging material.

Films From Biomonomers

Poly(lactic acid) (PLA)

In an attempt to improve the toughness of PLA and maintain transparency, blends of PLA and silicone were examined (Meekum and Khiansanoi, 2018). The intended application was frozen food packaging. The other additives in the experiment were 3-aminopropyltriethoxysilane (for crosslinking), a plasticizer (a polyester polyol), and talc. For 700 g of PLA, the amount of

silicone was varied from 0 to 12 parts per hundred (phr); one phr silane and 1 phr plasticizer were used in all the experiments to produce extruded strands. The strands were pelletized. A portion of the pellets were crosslinked by heating the pellets at 65°C and 100% RH for 12 h. The non-crosslinked and crosslinked systems were then processed into films.

Impact strengths of the PLA/silicone films were tested at room temperature and at approximately -98°C . Also tested were low density poly(ethylene) (LDPE) and neat PLA. At room temperature and for the unnotched specimens at the sub-zero temperature, the performance of LDPE was far better than that of the PLA/silicone films. However, for the notched samples, the crosslinked specimen with 8 phr silicone performed best. Specifically, at -98°C , the impact strength of the 8 phr crosslinked sample and LDPE were 8.32 kJ/m² and 3.62 kJ/m², respectively.

In order to improve the film forming process, Meekum and Khiansanoi (2018) experimented with various amounts of talc incorporated into the 8 phr crosslinked sample. They were able to produce acceptably reproducible, relatively transparent films. An optimal value of 40 phr talc was determined based on the ease of forming a film and relatively good tensile properties and impact strength values even though the addition of talc did decrease the impact strength for the notched specimen at -98°C . LDPE had a comparable impact strength to the talc-containing sample, but LDPE had better film forming properties.

In a different approach towards improving film from PLA, Mallegni *et al.* (2018) melt mixed PLA with either poly(butylene succinate) (PBS) or poly(butylene adipate-co-terephthalate) (PBAT) in the presence of an epoxy ring-containing plasticizer (polypropylene glycol diglycidyl ether). Additionally, the blends contained varying amounts of a nucleating agent (NA) (the potassium salt of dimethyl 5-sulfoisophthalate). The NA enhanced the rigidity of the blend sufficiently so that suitable pellets could be prepared.

The mechanical properties of the films with plasticizer and NA are shown in Table 3. Values obtained for pellets of PLA with or without the plasticizer and with no NA gave values similar to those shown for the Mallegni *et al.* (2018) films (Table 3). While there are challenges in preparing films from the PLA blends with PBAT or PBS and with the NA, the mechanical properties of these films are reasonably similar to the values for LDPE (Tables 1 and 3). Mallegni *et al.* (2018) also performed the Trouser tear test on the PLA/PBAT and PLA/PBS films. The results for the Trouser tear strength were 8250 N/m and 5700 N/m for the PLA/PBAT and PLA/PBS film, respectively. This compares well with the value for PP (5560 N/m); however, these results are quite less than the Trouser tear strength for LDPE (55,560 N/m).

In another clever approach (Goh *et al.*, 2016), graphene oxide (GO) and reduced graphene oxide (rGO) sheets were prepared and placed between two overlapping PLA films. To prevent delamination, the processing involved a binder and hot pressing to connect the PLA and the graphene materials. These systems (PLA-GO and PLA-rGO) and a control (PLA alone processed as were the graphene materials) were well characterized by scanning electron and atomic force microscopies (SEM and AFM), Raman and attenuated total reflection FT-IR (ATR) spectroscopies, X-ray diffraction (XRD), rheometry, and mechanical testing. From this, the differences in the GO and rGO sheets were established. Specifically, the reduction from GO to rGO gave a reduced material with sheets that stacked more closely than its precursor. This is obviously because of the reduction of the oxygen in GO. The data for oxygen and water permeability show the effect of this molecular change (Tables 1 and 3). The PLA sandwich containing rGO provided the best barrier to oxygen and water among the three samples examined. The permeability values obtained are comparable to others reported (Tables 1 and 3).

Goh *et al.* (2016) simulated the shelf life got PLA-rGO, PLA-GO, and the control. Their model was based on the oxygen permeation rate and the rate of oxidation of the packaged material (edible oil and potato chips). From the permeability data, clearly PLA-rGO had the best shelf life. Comparisons were not made with other packaging films. The authors also noted the PLA-GO was translucent and PLA-rGO was opaque; they noted that further work was needed to improve the transparency of PLA-GO and PLA-rGO if these materials were to be generally used for packaging.

Gupta and Katiyar (2017) reviewed previous work on stereocomplexation of PLA to produce a film with enhanced thermal, barrier, and mechanical properties. In their work, they grafted cellulose microcrystals (CMCs) to the D-enantiomer of lactic acid; CMCs were used to initiate the polymerization of D-lactide to PLA. The percent of CMC used for the polymerization was varied (1%, 5%, and 10% CMC). The biocomposite material was prepared by melt mixing equal amounts of the CMC-grafted D-isomer PLA and ungrafted L-isomer PLA. The resulting products were labeled as s-PLA-0.5%CMC, s-PLA-2.5%CMC, and s-PLA-5%CMC; the control was labeled as s-PLA.

DSC analysis resulted in the data shown in Table 4. s-PLA additionally showed endotherms at 151.8°C and 179.3°C, interpreted as due to melting of homocrystals of the two enantiomeric PLA systems. The biocomposite of these polymers without the influence of the grafted CMC is the melting endotherm at 211.1°C. Clearly the grafted system promotes the formation of the biocomposite. FTIR and X-ray diffraction results corroborate the DSC results in terms of structural changes upon grafting CMC to PLA. Examination of barrier properties gave further indications of the effect of the grafting. The oxygen permeability for s-PLA-5CMC was 25% less than that of the control (Table 3). For four different temperatures (15°C, 23°C, 35°C, and 45°C), the oxygen permeability decreased as the percent of CMC grafted to PLA increased. Interestingly, the water vapor barrier property showed significant improvement for s-PLA-2.5CMC compared to the control, s-PLA; however, there was only slight improvement for s-PLA-5CMC compared to s-PLA. The authors (Gupta and Katiyar, 2017) rationalized that the increase of CMC in the structure probably provided a denser structure to prevent water molecules from passing through the film, but also provided a larger hydrophilic area. The tensile strength of the grafted PLA biocomposite s-PLA-5CMC was significantly greater than the control s-PLA (Table 3). The percentage elongation at break also increased for the biocomposite relative to the control (Table 3). There is a remarkable difference in the percent elongation at break for s-PLA-0.5CMC relative to the control: 36% and 1.9%, respectively. For s-PLA-2.5CMC and s-PLA-5CMC, the percent elongation at break decreases to approximately 24% each. One rationale for this

Table 4 Thermal analysis of biocomposites from interaction of PLA L-isomer and CMC grafted to PLA D-isomer

Polymer	T_m , °C	ΔH_m , J/g
s-PLA	211.1	34.8
s-PLA-0.5CMC	209.1	48.2
s-PLA-2.5CMC	209.8	49.4
s-PLA-5CMC	208	15.2

observation is the even distribution of CMC provided by the grafting of CMC to PLA. SEM and AFM data corroborate this rationale.

A unique PLA film was prepared by incorporating a reinforcement prepared from chitosan and lactic acid (Pal and Katiyar, 2016). Seventy percent deacetylated chitosan and lactic acid were reacted by microwave heating at 110°C for thirty minutes under a nitrogen atmosphere. The resulting nanoparticles (OLLA-g-CH, oligomeric lactic acid grafted to chitosan) were characterized. FTIR analysis showed a new absorption at 1539 cm^{-1} interpreted as due to a primary bond between a chitosan amine group and a the carboxylic group of lactic acid; additionally, the X-ray and TGA data for OLLA-g-CH in comparison to appropriate chitosan and PLA controls supported the conclusion that a compound with lactic acid grafted to chitosan had been prepared. The OLLA-g-CH nanoparticles were incorporated into a PLA matrix at three different concentrations (1%, 3%, and 5%) and the films prepared from this composite (PLA/OLLA-g-CH, 1%, 3%, and 5%) were studied.

The PLA/OLLA-g-CH film study included determination of mechanical properties and of oxygen permeability (Table 3). Most notable among the mechanical properties is the increase in the percent elongation of the films as the percent of PLLA-g-CH is increased. Although the tensile strength of the composite films decreased as the percent OLLA-g-CH increased, the composite with five percent OLLA-g-CH showed promising mechanical properties as a packaging material. Additionally, the oxygen permeability decreased as the percent of OLLA-g-CH in the composite increased (Table 3); the oxygen permeabilities of PLA and of PLA/OLLA-g-CH, 5% are $1.65 \times 10^{-16} \text{ kg m/m}^2 \text{ s Pa}$ and $0.302 \times 10^{-16} \text{ kg m/m}^2 \text{ s Pa}$, respectively. The rationale for the improvement in oxygen permeability is interpreted as an interaction between PLA and the chitosan backbone of OLLA-g-CH giving a barrier network in the polymer system (Pal and Katiyar, 2016). The water vapor transmission rate (WVTR) determined for PLA and the PLA/OLLA-g-CH composites showed an increase as the percent OLLA-g-CH in the composite increased. Imagining the composite as a sea of PLA (the matrix; $M_n = 15 \times 10^4 \text{ Da}$ and $M_w = 20 \times 10^4 \text{ Daltons}$) containing nanoparticles that appear to be a chitosan head with a PLA tail ($M_n = 1.4 \times 10^3 \text{ Daltons}$ and $M_w = 3.0 \times 10^3 \text{ Daltons}$), the hydrophilic chitosan head most likely contributes to the WVTR for these systems. Even so, the TGA results (Pal and Katiyar, 2016) show far less water absorbed by the composite films than by the chitosan film.

Films From Bacterial Biosynthesis

Poly(hydroxyalkanoates) (PHA)

A nanocomposite of a PHA has been examined as a support for nisin, an antibacterial peptide. Specifically, poly(3-hydroxybutyrate)/polycaprolactone (PHB/PCL) (a blend) films reinforced with organoclays were studied (Correa et al., 2017). PHB is a renewable material. PCL is synthesized from the ring opening polymerization of caprolactone, which is synthesized industrially from cyclohexanone and peracetic acid; even so, PCL is biodegradable. Hence the PHB/PCL blend is a good candidate for an environmentally friendly material.

The barrier and mechanical properties of films of the blend and of the nanocomposites of the blend were determined (Table 3). As expected, the nanocomposite films (PHB/PCL/Clo 10A and PHB/PCL/Clo 30B) had improved water vapor permeability compared to that of PHB/PCL; the tensile strengths of the nanocomposites were greater than that of the blend. Although all three nisin-activated materials were effective against a meat-spoiling bacterium, the three samples were equally effective with no significant differences measured. The authors conclude that all three materials are potential candidates for meat packaging films.

Conclusions

Although this article is not a review, a clear observation that was apparent from the preparation of the article is that the effort to explore renewable thin films is global. While the quality of the work reported may be variable, the various approaches to find replacements for non-renewable films from fossil fuels provide a significant view of what is possible. Among the notable approaches are (1) the use of cellulose crystals and starch crystals in corn starch that provided significant improvement in UV protection (Ali et al., 2018); (2) a starch/lignin blend with a graphene oxide reinforcement that improved water vapor permeability and resistance to hydrolytic degradation and gave good mechanical properties (Aqlil et al., 2017); (3) the melt mixing of PLA with either PBS or PBAT, and other additive, that gave films with properties similar to those of LDPE (Mallegni et al., 2018); (4) the synthesis of a PLA-chitosan nanoparticle for dispersion in a PLA matrix to give films with good mechanical and oxygen

permeability properties (Pal and Katiyar, 2016); (5) the preparation of films for low temperature applications from cellulose crystals in a rubber matrix (Sun *et al.*, 2018) and from a crosslinked PLA/silicone blend (Meekum and Khiansanoi, 2018); (6) the sandwiching of a reduced graphene sheet between two PLA films to give films with improved oxygen and water vapor barrier properties (Goh *et al.*, 2016); and (7) the comparison and molecular dynamic calculations with experimental data on the mechanical properties of chitosan/nano-reinforced systems (Aztatzi-Pluma *et al.*, 2016).

In a glimpse of the future, it would be ideal if all commonly used materials could be prepared from renewable resources. Films used for packaging food is an example where the replacement of non-renewable and non-biodegradable films by renewable and biodegradable films will have a significant effect on the environment. The nature of packaging materials has evolved over time. As recently as the 1960s, multi-layer films, produced to protect food products were first made; these films were largely polymers synthesized from fossil fuels. Since the 1960s, the development of these films allowed for creative approaches to producing films that could protect against oxygen, moisture, carbon dioxide, ultraviolet light, etc., in order to protect packaged food. The manufacture of thin films for packaging from renewable resources could be another transformative step in the history of packaging. Assuming the desirability to use renewable and/or biodegradable materials in the production of packaging films, if there is an application and if the production cost is reasonably competitive, then this new class of packaging films will become part of this evolutionary pattern. Hopefully this article can assist in this development.

Renewable Agricultural Fibers as Reinforcing Fillers in Plastics: Mechanical Properties of Kenaf Fiber-Polypropylene Composites

Mohd H Othman, Tun Hussein Onn University of Malaysia, Johor, Malaysia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Renewable resources have created more demand and opportunities, to reduce problems such as pollution, climate change and resource reduction. More research had been developed to utilize these resources, for various types of application. For example, a renewable resource such as natural fibers could be used for insulation materials in structures, patch and orchard utensils, recycled packaging, makeups, and nutrition productions too (Ramesh, 2016).

One of the methods to use these renewable resources, such as the lignocellulosic fibers and wood/agricultural wastes is to use this material as fillers and reinforcing fibers in polymer matrix (Akil *et al.*, 2011). However, several issues need to be considered before blending these materials together, such as the preparation method, the appropriate and accurate ratio of reinforcement have been reported, with improved filler/matrix interaction, quality of dispersion of the reinforcement particles and the interfacial interaction between the matrix and the reinforcement (Utracki, 2004).

According to several previous reviews, it was stated that the progress of renewable agricultural is rapidly growing, because this material can be used over and over again, and the resources are able to be replaced naturally, with minimum impact to the environment. Above all fibers from natural resources, kenaf had been chosen by several researchers over the past few years, because it potentials in term of availability, market demand, preparation procedures and the fiber's exceptional properties. Since sustainability and green material was preferred nowadays, using kenaf fiber as the reinforcing fillers for plastic composites will motivate scientists and manufacturing engineers, as this article provides the extension of previous review to address more important notes for future references (Akil *et al.*, 2011).

In this article, mechanical properties of kenaf fiber-polypropylene composite has been elaborated. As for mechanical and physical testing, which are normally performed towards composite materials, standard tests such as high-force tension (tensile), compression, impact, flexural, shear, rheology, and fatigue are known. Interestingly, the physical testing includes density, void content, water absorption, hardness, and scratch resistance. Currently, polymer and polymer composite tests have been standardized by a number of organizations by leading manufacturers and research institution, such as ASTM, ISO, CEN and other standards (Saba *et al.*, 2019).

Utilization of Kenaf

Kenaf is an annual plant originating from West Africa, growing to 1.5–3.5 m tall with a woody core. The stem's diameter is 1–2 cm and they are often, but not always, branched. The fruit is a capsule 2 cm in diameter, containing several seeds. The stem contains a bast fiber portion comprising 26%–35% (by dry weight). The average length of the fiber is 2.5 mm (Pari *et al.*, 2014). Kenaf shows robust mechanical properties. In recent years, two main reasons have contributed to the very high interest in kenaf cultivation. Kenaf has ability to absorb nitrogen and phosphorus within the soil. Kenaf also able to accumulate carbon dioxide at a significantly higher rate (Aji *et al.*, 2009). India and China are the most important producers of kenaf (Carus *et al.*, 2014). Kenaf is mainly grown in China and Indonesia, and can be grown for various applications. The crop has traditionally been used to produce fiber and food. The fibers can be used to make cordage, rope, burlap cloth, and fishnets because of its rot and mildew resistance. Besides these traditional applications, there are also a number of new uses, such as paper pulp, building materials, biocomposites, bedding material, oil absorbents, etc. Recently it has also come to be considered an important medicinal crop, as its seed oil able to cure certain health disorders and help in controlling blood pressure and cholesterol (Monti and Alexopoulou, 2013).

Kenaf fibers are used as reinforcement or filler in polymer composite materials, which are used increasingly in the automotive industries. Kenaf fiber composites are used in automotive applications, mainly because of its light weight and end-of-life properties (Monti and Alexopoulou, 2013). The growing demand for kenaf in the automotive industry stems mostly from the explicit wishes of some OEMs. In this context the following considerations arise (Carus *et al.*, 2014):

- Non-woven producers are reporting high fiber losses during the processing of kenaf fibers.
- Water retting is practiced to obtain the desired fiber qualities. However, water retting implies negative ecological effects (biochemical oxygen demand of the retting water) and negative social impacts (mostly working conditions and wages) in the fiber producing countries, e.g., Bangladesh, India and Indonesia.
- Nevertheless, the quality of water-retted kenaf fibers make them especially interesting for the automotive industry, since they allow for very thin laminations on composites, which are desirable for the design and weight reasons.
- It is not easy to distinguish kenaf fibers from jute fibers, so customers cannot always be certain that their bale labelled "kenaf" does not contain any jute. In the textile process chain, jute is treated with batching oil to make the fibers easier to process. Due to fogging problems, fibers treated with batching oil are not acceptable in the automotive industry. Though if jute fibers that are free of batching oil are used, there is no fogging and they can be processed just as well as kenaf, sometimes even better.

Natural fibers are relatively easy to obtain at a high yield and high specific surface area and can be treated chemically to compete with synthetic fibers. Hence, to study the mechanical properties of fiber-reinforced polymers, certain issues associated with the fiber-matrix condition needs to be solved first. A number of factors such as the matrix and fiber selection, fiber dispersion and orientation, and pretreatment of fibers can be used to tailor the mechanical properties of the fiber-reinforced polymer. The influence of fracture toughness, the compressive response and failure characteristics of natural and synthetic fibers have been analyzed and reviewed by several researchers. It was found that the hydrophilic nature of fibers leads to reduce the compatibility of the fiber with hydrophobic polymers, which has a negative effect on fracture toughness (Ghalia and Abdelrasoul, 2019). To quote one example, the performance of ultra-high molecular weight polyethylene/high density polyethylene-reinforced kenaf composites had been analyzed in terms of tensile, flexural (three-point bending) and an impact test (Charpy). The tensile results of these samples are significantly higher (20%) than pure blend resin. However, the flexural and Charpy strengths showed the drawback results, whereby the performance of composite is reduced (Mokhtar *et al.*, 2013).

As for the potential of kenaf, some researcher have recommended kenaf as the additional fillers that could improve the engineering behavior of sand-clay mixtures. The reinforcement of structural elements and construction materials using natural fibers have gained popularity among researchers and industries due to environmental concerns and financial problems of synthetic fibers. The contribution of natural fibers as soil reinforcement elements enhances the shear strength properties as the stresses in the soil mobilize tensile resistance in the fibers. Based on the results, the addition of a certain amount of kenaf fiber to the sand-clay mixture enhances the mixture ductility, improves the shear strength parameters, and ultimately makes it an appropriate candidate to be used in construction projects such as pavement layers, slope protection, embankment, and building foundation (EsmaeilpourShirvani *et al.*, 2019).

Kenaf Fibers–Polypropylene Composites

Kenaf was originated from *Hibiscus Cannabinus L* family *Malvacea*, a cellulosic source which could be harvested after sowing the seeds within a three month period, with capability to nurture under various condition of weather. The average height of this plant is 3 meters and above, with the base diameter of 3–5 cm. Several characteristics could be gained from kenaf fiber, with a few advantages as compared with common plants such as (Akil *et al.*, 2011):

- (1) Light-weight and cost-effective.
- (2) Remarkable papermaking features.
- (3) Requires much less energy compared to synthetic fibers.
- (4) A good rotation crop for maize, groundnuts, with capability to enrich the land.
- (5) The ability to absorb nitrogen and phosphorus.
- (6) Significantly higher carbon dioxide absorption rate.
- (7) Higher photosynthesis rate as compare with typical plants.

By integrating this plant for value added outcomes, kenaf had become the preferred crops, as compared with wood that was typically used in pulp and paper industries. Hence, kenaf could reduce or eliminate the forest destruction. However, recent progress had stated that the usage of kenaf in paper production is still very limited. One of the reasons is the suitable part of kenaf that for paper is a bast fiber, which only consist of 35% of kenaf structure, whereas 65% underutilized part of kenaf is the core. Therefore, more attempts had been made towards utilizing kenaf, such as preparing the kenaf as woven and non-woven textiles. Besides that, a number of research had discovered the potential of kenaf as a reinforcing fiber in thermoplastic composites, based on the findings that shows the composite had the superior toughness and high aspect ratio in comparison to other fibers (Akil *et al.*, 2011).

As mentioned before, researchers have discovered the possible use of kenaf as an alternative reinforcement material. One of the examples is by incorporating kenaf fiber into the polypropylene matrix. First of all, practically kenaf fibers offer a low cost-massive volume of resources, similar with polypropylene. Polypropylene (PP) is a thermoplastic commodity polymer from the group of polyolefins, used in diverse applications. It is produced through chain-growth polymerization of the propylene monomer, partially crystalline and non-polar. Based on a review, the mixture of kenaf and polypropylene is good in improving certain features of the polypropylene. The mechanical properties of kenaf fiber-polypropylene composite is equivalent to certain properties of materials, such as glass fiber polypropylene. Diverse range of structural and non-structural, industrial products could be prepared from this material. However, some drawbacks have been reported whereby kenaf fiber-polypropylene composite absorb more water and low notched impact strength. To overcome the high water absorption problem, thorough consideration has to be made before using these composites as water's absorber. As for lower resistance towards impact can be solved by using impact-modified polypropylene copolymers and flexible maleated copolymers, although the modulus and tensile strength could be compromised. The most interesting part in the effect of higher fiber volume fractions. Some of the findings have stated an interesting point to note that the agro based composites are better, compared to those of the inorganic-filled systems. This finding is important since the cost of material could be reduced, as well as the energy usage, instead of producing the high energy utilizing glass fibers or mined inorganic. Other issues that need to be controlled is the dispersion and adhesion between the nonpolar polypropylene matrix and the polar lignocellulosic fibers. These are the critical factors that need to be controlled, so that it is easy to determent the properties of the composite. More study had been carried out towards the usage of functionalized additives to improve the dispersion and the interaction between cellulose-based fibers and polyolefins, such as maleic anhydride grafted polypropylene (Sanadi *et al.*, 1995).

Preparation and Treatment

The preparation kenaf fiber-polypropylene composite was very important, since it shall provide better results and properties. For instance, the usage of high shear mixing technique from the thermokinetic mixer could produce better fiber attrition. Higher strengths could be obtained if alternate processing techniques are developed to reduce the amount of fiber attrition, and to get better fiber dispersion (Sanadi *et al.*, 1995).

Most of the research used compression molding as the preparation technique for kenaf fiber-polypropylene composite. As for an example, a research had use compression molding to fabricate kenaf fiber-polypropylene composite sheets. A thermoformed composite promotes more potential applications, and equivalent to current synthetic composites. The preparation of these sheets needs to be optimized, so that it could produce a good outcome. The compression molding process was executed by applying kenaf fibers with layered sifting polypropylene in a form of micro fine powder. Based on the findings, the tensile and flexural strength of kenaf fiber-polypropylene composite is comparable 40% by weight with polypropylene composite that used hemp and flax as their fibers, and higher when equated to polypropylene-coir and sisal composite. Furthermore, kenaf fiber-polypropylene composite also provide higher modulus per cost and specific modulus than sisal, coir, hemp, flax and E-glass. This condition can be achieved by controlling the temperature of the die and preform. The temperature should be elevated so that the cooling and tearing during forming could be avoided (Zampaloni *et al.*, 2007).

Researchers work also finds that controlling and optimizing the processing conditions/techniques have the remarkable consequence of the mechanical properties of fiber reinforced composites (Saba *et al.*, 2015). For instance, a research performed the optimization of processing conditions towards the long kenaf fiber-polypropylene composite. The compression molding machine was chosen to prepare the product, with the arrangement of component as displayed in Fig. 1. It was found that the tensile and impact strength was affected by the processing conditions, whereby better results could be obtained through the optimal setting. The setting was optimized, as the temperature of 230°C and a barrel speed of 16 Hz (Bernard *et al.*, 2011).

More research had been carried out towards the mechanical characterizations of kenaf fiber polypropylene composite, by using non-woven materials, with optimum processing condition. Fig. 2 shows the fiber images of the non-woven kenaf and polypropylene. The optimum condition was 230°C for temperature and 60 s for compression time. The results found that linear elastic behavior within valid strain range of 0%–0.5% of uniaxial tensile test and 0%–1% of flexural test. The open-hole test shows that the strength-reducing effect of stress concentration is mitigated greatly by the ductile-like behavior of kenaf fiber-polypropylene composite. Besides that, these composites also sensitive to strain rates (Hao *et al.*, 2012).

Based on a review made towards the factors that affecting the mechanical properties of kenaf fiber-polypropylene composite, one of the factors was the pretreatment process during the fabrication of this material. Before combining the kenaf fiber in the polypropylene matrix, a pretreatment is a necessity since it improves the properties of mechanical and tensile, by promoting good adhesion or interfacial linkage between fiber and matrix. The improved adhesion was obtained because the surface of kenaf fiber was cleaned and modified chemically. Moreover the moisture absorption process is reduced with the expansion of surface unevenness. Other pretreatment process which is typically available in industry also can be performed towards these fibers, as displayed in Fig. 3. Other than that, coupling agent also can be used to improve the interface linkage of fiber/matrix (Saba *et al.*, 2015). To quote an example, some researchers had performed an alkali-silane treatment towards short fiber non-woven kenaf fiber that's used polypropylene as their matrix. The responses of the treatment were tensile and flexural strength. According to the findings, the tensile and flexural strength were getting better. Based on the scanning electron microscopy observation, best result was obtained from the good interfacial bonding of fiber/matrix. The highlight of this research is the optimum concentration of sodium hydroxide (NaOH) was 6%, and 30% by mass of kenaf in this composite are comparable to glass fiber composites (Asumani *et al.*, 2012).

More study had been carried about the utilization of coupling agent to improve the surface properties of kenaf fiber-polypropylene composite. In this research, the type of coupling agent that was used was a protein extracted from corn, typically known as zein. Based on the results, the zein coating of nonwovens kenaf was enhancing the flexural, viscoelastic properties, storage modulus and stiffness in composites. A slight decrease of thermal stability was also found in the chemical modification of kenaf nonwovens (John *et al.*, 2010). As for another example, a research had discovered that the alkali treatment combined with three-aminopropyltriethoxysilane treatment for kenaf fibers had improved the tensile and flexural properties. The properties are considerably better than those obtained from either alkali or silane treatment alone (Akil *et al.*, 2015). However, certain precautions need to be noted as awareness, such as (Ramesh, 2016):

- Chloride in clean water that was used in retting process during fiber extraction could cause fiber structure's damage, thus weakened the mechanical properties.
- There is no difference in term of fiber tensile strength, between natural pond, artificial pond with natural water and river water, if these waters were used in the retting process for initial treatment.
- If the NaOH solution was selected, it is not recommended to use more than 8%, because it can cause the fiber damage, lots of wrinkles, smaller diameter and brittle.

Some of the researchers had prepared and characterized short kenaf fiber-based biocomposites reinforced with multi-walled carbon nanotubes. The specimens were produced by melt blending process in an internal mixer. Based on the results, The optimum in mechanical strengths was detected at 1 wt% multiwall carbon nanotubes (MWCNTs) and the values of the different weight loss temperatures and second decomposition peak temperatures increased after incorporation of MWCNTs due to the barrier effect of the MWCNTs. Morphological study, which characterized using scanning electron microscopy (SEM) technique verified that a good and homogeneous distribution of MWCNTs through the biocomposites. However, some aggregates were revealed at higher MWCNT content (Yaghoobi and Fereidoon, 2019).

The Fiber Content's Effects

Beside pretreatment, the amount of fibers or fiber contents also affecting the mechanical properties of this material. Besides that, the fiber size and the aspect ratio also need to be monitored, because high ratio will transfer the stress efficiently in the matrix (Saba *et al.*, 2015). According to a review, at this moment, 60% by weight of kenaf fiber content was the maximum amount that is allowed to reinforce the kenaf fiber-polypropylene composite. More research and innovations were needed to increase the kenaf fiber content for commercial use, whereby close monitoring was required to maintain the sufficient properties of the composites. For instance, an innovative approach had been performed, by adding a special process to compound 85 wt% of kenaf fiber in polypropylene matrix. The results show that the composite had produced good modulus of rupture (MOR)- flexural strength and a modulus of elasticity (MOE)- flexural stiffness which was equivalent to common fiberboards (Sanadi *et al.*, 2002).

Another example of research that studies the effect of different fiber content was carried out by using dynamic mechanical analysis. Two types of formulation were prepared for kenaf fiber-polypropylene composite with different fiber content. As compared to original resin, it was found that the mechanical loss factor (damping) was decreased. In the other hand, the storage and loss moduli were increased, proving that the kenaf had efficiently reinforced the polypropylene matrix. More than that, there are shifting in the terms of glass transition towards the lower temperature, and the increase of temperature intensity also occurred (Tajvidi *et al.*, 2006). Additional study also had proven that kenaf fiber in powder form, with different loading, had provided adequate reinforcement to increase the strength of the polypropylene. However, this research promotes the use of coupling agent, to achieve better fiber/matrix interfacial bonding (Zampaloni *et al.*, 2007).

Morphology and Mechanical Properties

Several reviews have been made towards the morphology and mechanical properties of kenaf fiber/polypropylene composites. As for morphology studies, a research had presented the thermograms of wide endothermic of differential scanning calorimetry, demonstrating the existence of moisture. The content of moisture needs to be reduced or eliminated because it can weaken the mechanical properties. Other than moisture, the crystallization also needs to be monitored because it can affect the recrystallization, melting and spherulitic architecture. The thermograms also indicated a shift in melting temperature towards the lower temperature, nevertheless increases in enthalpy values. When the onset of recrystallization increased, the added fibers changed the crystallization by providing nucleation sites for the polymer. It is important to control the length of fiber, because more fiber tips will affect the nucleation. The fiber also influences the rate of crystallization and surface roughness, whereby the viscosity of the composites could be modified. As for the findings from the scanning electron microscope micrograph, it was displayed that the main failure factors of these composite structures were influenced by the fiber pull out and breakage (Ramesh, 2016).

In terms of mechanical properties, kenaf fiber-polypropylene composite had better properties as compare with typical fiber-polypropylene composites. For instance, the flexural and tensile modulus for 50% by weight of kenaf fiber-polypropylene are better than glass fiber-polypropylene and mica fiber polypropylene. More comparison had been made towards other types of fillers such as calcium carbonate, newspaper fibers, and talc. It was found that 40% by weight of kenaf fiber-polypropylene are much more superior to these fillers (Akhtar *et al.*, 2016). However, several factors need to be deliberated before obtaining the benefits of mechanical properties from kenaf fiber-polypropylene composite. The factors were displayed in Fig. 4 (Ramesh, 2016).

The specific properties of the natural fiber composites were in some cases better than glass fiber. Hence, the natural fiber composites have a potential to replace glass in many applications that do not require high load bearing capabilities. The relationship between tensile modulus of the kenaf composites with fiber weight fraction is demonstrated in Fig. 5. The results show an increase in the tensile modulus with increasing fiber weight fraction. Additionally, the effect of fiber weight fraction on the impact strength is indicated in Fig. 5. A moderate increase in impact strength is seen between 30 and 40% fiber weight fraction and a sharp increase from 40% to 50% fiber weight fraction. A larger serrated fracture surface was noted at 50% fiber weight fraction compared to the case at 30% fiber weight fraction of the composites, where the fracture surface was more or less flat. The serrated failure mode absorbs more energy than a sharp fracture. The failure mechanism was mainly by fiber pull out due to the weak interface strength between the fibers and the matrix (Wambua *et al.*, 2003).

More study had been conducted towards the development of thermoplastic elastomer composite reinforced with 20 vol% kenaf fiber. Two types of impact modifier were blended with polypropylene namely; thermoplastic natural rubber (TPNR) and polypropylene/ethylene-propylene-diene-monomer (PP/EPDM). It was found that the tensile strength for TPNR is about 12%

Fig. 5 Effect of fiber weight fraction on the tensile modulus and impact strength (Charpy) of kenaf fiber reinforced polypropylene composites. Credit to: Wambua, P., Ivens, J., Verpoest, I., 2003. Natural fibers: Can they replace glass in fiber reinforced plastics? *Composites science and technology* 63 (9), 1259–1264.

Table 1 Summary of kenaf fiber-polypropylene properties

No	Properties	Details
1.	Strength and modulus	● Tensile strength increase. ● Small improvement in flexural strength. ● The tensile modulus improved by adding more fibers. ● Higher modulus for composites (uncoupled).
2.	Failure strain and tensile energy of absorption	● More fibers could reduce the failure strain, due to the restriction towards molecules mobility. ● The addition of fibers also reducing the tensile energy absorption, whereby the energy absorbed was leveled off at 35 volume percentages of fiber.
3.	Impact properties	● Regardless the sample was notched or unnotched, the impact properties of this material were subjected to standard test and fiber content. ● For instance, at 45% of the fiber, the impact strength was improved. ● More fiber would create the stress concentration region that needs less energy to crack. Hence, the interfacial bonding of fiber/matrix has to be monitored.

Note: Sanadi, A.R., Caulfield, D.F., Jacobson, R.E., Rowell, R.M., 1995. Renewable agricultural fibers as reinforcing fillers in plastics: Mechanical properties of kenaf fiber-polypropylene composites. *Industrial & Engineering Chemistry Research* 34 (5), pp. 1889–1896.

higher than the PP/EPDM matrix. The present of kenaf fiber and maleic anhydride grafted polypropylene (MAPP) however, has significantly increased the tensile strength of the PP/EPDM composite by approximately 81%, while only 55% increment attained in TPNR–Kenaf fiber–MAPP as compared to unreinforced TPNR. Apart from that, flexural properties and impact strength are greatly improved for kenaf fiber composite (treated). This shows that kenaf fiber has imparted its tensile strength to the PP/EPDM system with good interaction provided by the compatibilizer agent. Scanning electron micrographs (SEMs) revealed that the improvement achieved in mechanical properties was due to the interaction between both matrix systems and kenaf fiber (Anuar and Zuraida, 2011).

As for another example of research, a lightweight laminate composite made from kenaf fiber/polypropylene was fabricated. The results show that the flexural modulus increased with increasing number of kenaf layers and heating time. The research also concluded that by using the optimized kenaf weight fraction, a maximum flexural modulus of the composite specimen shall decreased with the decrease of the bulk density (Shibata *et al.*, 2006). **Table 1** shows the summary of mechanical properties that could be obtained from kenaf fiber-polypropylene composite (Sanadi *et al.*, 1995).

Renewability, Recyclability and Sustainability

The awareness towards the environmental issues such as global warming, emission of toxic pollutants and contaminants in the sea, air and on land, destruction of biodiversity and the needs to meet the sustainable development goals, has stimulated interest in the development of recyclable and eco-friendly single polymer composites. The comparison had been made to the heterogeneous composites, fully recyclable and therefore providing economic and environmental advantages. An increasing trend is the use of natural fiber reinforced composites as low-cost composites with low density and high specific properties, non-abrasive and

biodegradable. The major challenge in the fabrication of single polymer composites is the small melting temperature difference between the fiber and the matrix, and in the case of natural fibers, the incompatibility of the fibers with the matrix, and the poor resistance to moisture (Abdullah *et al.*, 2019). When natural fibers are closely compared to inorganic fibers, it presents some well-known advantages such as lower density and cost; are less abrasive to the processing equipment, easy to modify the fiber surface, and its relative non abrasiveness. Furthermore, they are recyclable, easily available in most countries, harmless, biodegradable and renewable. (Li *et al.*, 2008). So, the renewability of kenaf fiber-polypropylene composites was typically associated with the renewability of kenaf as natural fiber.

Environmental concerns have attracted researchers to recycle composite materials and thermoplastics due to the desire not to waste materials and reduce disposal of scraps that may eventually pollute the environment. Hence, more studies associated with kenaf recycling had been carried out, such as the effect of recycling on the mechanical properties of kenaf fiber/polyethylene terephthalate reinforced polyoxymethylene hybrid composites. The result shows that the tensile strength after second recycling process is lower compared to the virgin hybrid composite. The impact strength also dropped to 4.3 J cm^{-1} as against 10.5 J cm^{-1} for the virgin hybrid composite. In the other hand, there was a significant increase in flexural modulus compared to the virgin hybrid composite. The results of thermal degradation showed about 80% weight loss for kenaf fiber between 300°C and 350°C . This condition happened because of the degradation of cellulose and hemicellulose content of the fiber. The percentage water absorption of the recycled composite dropped by 80% compared to the virgin hybrid composite (Dan-mallam *et al.*, 2014).

Some of the researchers try to blend the kenaf fibers with recycled plastics or low-cost polyethylene in form of post-consumer film wastes and shrink wraps. Manufacturing tests were conducted at the U.S. Forest Products Laboratory, showed that kenaf stems can be used as filler in virgin plastics to yield impact properties, similar to wood-filled composites. However, the deficiency of the kenaf-based composites was the low tensile strength which suggests that they should not be utilized in systems requiring high tensile property. Recyclable and environmental-friendly products could be produced from kenaf fibers with potential used in industries like the container and the automotive industry (Chow *et al.*, 1998). Another project that used recycled polypropylene (rPP)/recycled polyamide 6 (rPA6) reinforced with kenaf had been conducted, whereby the composites thermal properties, processing behavior and morphological study were investigated. Based on the findings, instead of the decrement in impact properties, other mechanical properties were improved when the compositions of kenaf were increased. However, it was difficult to process the high composition kenaf by using the typical injection molding machine as the melt flow index values increased. Scanning electron microscopy (SEM) micrographs showed an improvement in the dispersion of kenaf in the matrix when kenaf compositions were increased. The overall results showed the best composition of kenaf was at 30 wt% (Arsad *et al.*, 2013). The recycling frequency also had been studied, whereby the properties of polypropylene-based composites reinforced with kenaf fibers were investigated with respect to their recyclability. As for the results, the recycling processes do not induce very significant changes in flexural strength and thermal stability of the composites. In particular, polypropylene-based composites reinforced with kenaf fibers are less sensitive to reprocessing cycles as compared with polypropylene-based composites reinforced with rice hulls (Srebrenkoska *et al.*, 2008). More than that, the recycled polypropylene kenaf composites also can be utilized for inflammability and biodegradability of biocomposites improvement. The example of materials formulations content that could be used as a fire retardant were recycled polypropylene, modified acrylic acid, reinforcement kenaf fiber, the mixture of magnesium hydroxide and aluminum hydroxide, without or with boric acid (Suharty *et al.*, 2014).

More research had utilized the recycled polypropylene reinforced with kenaf fiber. These composite comes with the improved interfacial adhesion between fiber and recycled polypropylene (RPP) matrix. The improvement was carried out by performing fiber surface modification through ultrasound treatment. Maleic anhydride grafted polypropylene (MAPP) was used as a coupling agent. The composites were examined by mechanical test, melt flow indexing test, scanning electron microscopy, thermogravimetric analysis (TGA), and differential scanning calorimetry (DSC). Water uptake analysis and accelerated weathering test were also carried out to find the suitability of the composites in outdoor application. Among the raw fiber contents ranging 10–50 wt% in the composites, the maximum tensile strength was observed at 40 wt% fiber loading without using MAPP. Treated fiber based composite with MAPP promotes the maximum of tensile, which is 57% higher than that of untreated composite. TGA and DSC analyses exhibit an enhancement of thermal stability for composite with MAPP. Incorporation of MAPP in the composites shows higher activation energy, suggesting improved interfacial bonding between fibers and matrix (Islam *et al.*, 2013). This research was continued by characterizing the laccase-treated kenaf fiber reinforced recycled polypropylene composites. Raw and laccase-treated kenaf fiber was used individually to reinforce RPP using extrusion and injection molding. Laccase was used to modify the surface of the fiber to improve the compatibility between fiber and matrix. Enzyme concentration and soaking time were considered as the treatment parameters. Based on the findings, the optimum fiber loading of 40% gave the highest tensile properties. Tensile strength improved due to coupling agent by 37%, whereas treatment of fiber did the same by 40%. Flexural, impact, and thermal properties of the composites and crystallinity of the matrix were improved due to treatment. Morphological images of the composites showed better adhesion, and moisture absorption was reduced by 37% due to treatment and use of coupling agent (Islam *et al.*, 2013).

In terms of sustainability, the carbon footprint of kenaf can be used as the guide. A system had been studied by adopting from cradle to grave concept of kenaf fiber production. The cultivation and fiber processing are anticipated to take place in India and Bangladesh. Transportation to the harbor in Hamburg, Germany, happens via ship and continues with lorry to the factory gate of the nonwoven producer in Germany. Typically kenaf is cut and water retted like jute. After retting, the fibers are manually extracted from the stems, then washed and sun dried. These activities are done manually by farmers, but not all agricultural and

decortication steps are done manually: some field applications involve tractors. Lastly, the dried fibers is delivered in rough fiber bundles to the so-called “fine-opening-processing” site, where they are refined and cut into the desired length for selling to the non-woven producer. These finishing steps are done with machines. Regarding the kenaf scenario, the fertilization is the main contributor to kenaf’s carbon footprint. The carbon footprint of the kenaf fiber scenario is 767 kg CO₂-eq/tons of kenaf fiber. In contrast to hemp and flax, kenaf plants are generally cultivated manually, but sometimes small tractors are also used for this kind of work. Because of manual field operations, emissions stemming from this process are quite small. On the other hand, emissions from transporting the kenaf from Asia to Europe have to be taken into account as well (Barth and Carus, 2015). According to (ISCC, 2013), it states a seventh principle, which deals with the designation of greenhouse gas emissions and which needs to be applied for the production of biomass. Hence, the development and utilization of kenaf fiber with polypropylene should consider the listed principles in order to achieve the suitability goals. The principles are:

- (1) Biomass shall not be produced on land with high biodiversity value or high carbon stock. High conservation areas shall be protected.
- (2) Biomass shall be produced in an environmentally responsible way. This includes the protection of soil, water and air and the application of Good Agricultural Practices.
- (3) Safe working conditions through training and education, use of protective clothing and proper and timely assistance in the event of accidents.
- (4) Biomass production shall not violate human rights, labor rights or land rights. It shall promote responsible labor conditions and workers’ health, safety and welfare and shall be based on responsible community relations.
- (5) Biomass production shall take place in compliance with all applicable regional and national laws and shall follow relevant international treaties.
- (6) Good management practices shall be implemented.
- (7) Calculation and verification of greenhouse gas emissions must be provided by the biomass producer.

Industrial Applications and Developments for the Future

Most of the applications were proposed based on the kenaf fiber-polypropylene composite mechanical properties. However, other properties could bring more applications. For instance, based on a review, the sound insulation test had been carried out towards these composites. It was verified that there are relationship between mechanical properties and acoustical behavior. This verification was described by the panel resonance theory, indicating that the classic panel resonance theory. Other than that, the utilization of kenaf fiber-polypropylene composite also have some benefits in terms of the thermal behavior. For instance, the test of heat deflection temperature or heat distortion temperature had produced a higher heat deflection characteristic than pristine polypropylene. A wear test also had been conducted, with the results shows that the fiber orientation, applied load and sliding velocity have a significant effect on the wear properties of kenaf fiber reinforced composite laminates. The wear mechanisms of the composite were also predominated by micro-cracks and debonding in the fibrous regions and deformation in the resinous regions. Hereafter, any product associated to wear and tear should take this substance into deliberation. Even though kenaf fiber-polypropylene composite had many potential and applications, precaution was needed to ensure the reliability of the product to be maintained. For instance, the exposure of the kenaf fiber reinforced composites to environmental conditions such as distilled water, sea water and rain water may result a decrement of fracture toughness. However, this condition relies on the content of the fiber, fiber orientation, area of exposed surface, and permeability of fiber, void content and the hydrophilicity of the individual component (Ramesh, 2016).

Another potential application of kenaf fiber that can be considered is to use kenaf as a bulletproof vest. A research had stated some findings about the tensile and flexural characteristics and high-velocity impact properties of a new composite material aimed to replace the current insert plate for existing available bulletproof vests or body armor. In this design, materials used are a kenaf, and x-ray film. Results showed that the designs enabled the material to absorb some impact energy because it was able to bounce back bullets shot (Azmi *et al.*, 2019).

Natural fibers have recently become attractive to the automotive industry as an alternative reinforcement for glass fiber reinforced thermoplastics. The best way to increase the fuel efficiency without sacrificing safety is to employ fiber reinforced composite materials in the body of the cars so that weight reduction can be achieved. A research has focused on partially eco-friendly hybrid long fiber reinforced thermoplastics with natural kenaf fiber to enhance the desired mechanical properties for car bumper beams as automotive structural components. The comparison had been made with a typical bumper beam material made from long fiber reinforced thermoplastics (LFRT). The results indicate that some mechanical properties such as tensile strength, young’s modulus, flexural strength and flexural modulus are more advantages to LFRT, the new material also must improve the ability to absorb more impact load and increase the protection of the front car component (Jeyanthi and Rani, 2012).

Another potential of kenaf fiber reinforced composites is to be used as electronic products. Some researchers have developed high-performance biomass-based plastics that consist of polylactic acid (PLA) and kenaf fiber, which fixates CO₂ efficiently. Adding this fiber to PLA greatly increases its heat resistance (distortion temperature under load) and modulus and also enhances its crystallization, so the ease of molding this material is improved. Eliminating the short particles from the kenaf fiber improves its effect on the impact strength. Furthermore, adding a flexibilizer (a copolymer of lactic acid and aliphatic polyester) to the

Fig. 6 Potential application of kenaf fiber-polypropylene composite. Note: Ramesh, M., 2016. Kenaf (*Hibiscus cannabinus* L.) fiber based bio-materials: A review on processing and properties. *Progress in Materials Science* 78, pp. 1–92.

composites improves their strength. These composites (PLA/kenaf fiber and PLA/kenaf fiber/flexibilizer) show good practical characteristics of housing materials of electronic products in comparison with petroleum-based plastics used in housing such as glass-fiber-reinforced acrylonitrile-butadiene-styrene (ABS) resin (Serizawa *et al.*, 2006).

Kenaf composite also can be used as insulation boards. An eco-profile of the kenaf-fiber thermal insulation board has been defined and, on the basis of a life-cycle approach, the energy and environmental benefits and drawbacks associated with its use in residential buildings have been assessed. The kenaf-fiber based products become widely the less impacting ones if different disposal scenarios are adopted. Finally the energy saving during the building operating time results largely higher than the global energy consumption related to the kenaf insulation board life-cycle. This confirms the large energy and environmental advantages related to the employment of insulating materials (Ardente *et al.*, 2008). Based on the benefits that were obtained by combining kenaf fiber with polypropylene, industries are willing to invest their capital in producing several products, made from kenaf fiber-polypropylene composite. Some of possible application of kenaf fiber-polypropylene composite are displayed in Fig. 6 (Ramesh, 2016).

Research about biocomposites had created remarkable achievements to replace conventional non-biodegradable petroleum-based materials. Bio-based materials could provide solutions for petroleum shortage and waste management problems. The specific focus has been given to wood-derived polymers (lignin, hemicelluloses, and cellulose) for production of bio nanocomposites. Large-scale productions of bio-macro/micro/nanocomposites at pilot/industrial scale and various fundamental and technical challenges in production (both in lab and pilot scale) have been given priority for further development (Nagalakshmaiah *et al.*, 2019). As for future development, kenaf fiber reinforced composite has a good prospect to be utilized in various manufacturing processes that have never been associated with other natural fibers before, such as pultrusion and filament winding. According to the previous review, the use of kenaf fiber reinforced composite in building and construction, is highly possible due to two main factors, which are low in cost and lightweight material (Thiruchitrabalam *et al.*, 2012). Moreover, recent development had concentrated more towards sustainable materials and manufacturing, whereby more focus and research had aimed towards renewable and biodegradable resources. Kenaf, also comes in the several forms and shape, also can be planted in different region will inspire the researcher to study the effects and propose more applications in wider aspects of industries. By solving the ecological issues, the massive usage of kenaf fiber may reduce pollutions towards atmospheric and water, showing it has a brighter future as compare to other industrialized fibers. However, treatment of effluents, disposal of waste and packing material and recycling issues will also require enormous capital outlays motivate the usage of these composites (Ramesh, 2016).

In the Industrial Revolution 4.0 (IR4.0) era, some of the key content of future technology is related to the Internet of Things (IoT), Cyber Physical System (CPS), Information and communications technology (ICT), Enterprise Architecture (EA), and Enterprise Integration (EI) (Lu, 2017). Hence, these technologies can be supported through computer modeling and simulation. Future development of research related to composites, modeling and simulation also had become the trend among researchers. For instance, a paper introduces a numerical model of kenaf composites, made from the unsaturated polyester matrix reinforced with unidirectional kenaf fiber. Two different dynamic failure models, both the ductility and shear failure models were described in the matrix. Hashin's failure criterion was used for the fiber to predict the mechanical behaviors of the kenaf composite under distinct high strain rate loading. It was found that the developed meso-scale model is found to be effective in providing detailed information regarding the deformation and stress distribution of the kenaf composites to obtain a better understanding of the mechanical response of the constituent materials under different loading conditions (Seman *et al.*, 2019). More research had been carried out about the input for computer simulation, such as a research about the inverse method for identifying the material properties of a kenaf reinforced composite test model. An initial finite element model of the composite test model is developed and normal modes analysis is carried out to calculate the modal parameters of the initial finite element model. It was found that the identified material properties are well matched with that of previously published papers in terms of the reduction in total errors (Peter *et al.*, 2019).

Conclusion

Explorations on kenaf fiber reinforced composite have created more influence among researchers due to the ecological factor, as well as the cost and the properties gained from this composite. This article had provide summaries in term of why kenaf fiber and polypropylene were chosen to be combine, the preparations and treatments needed, the effect of fiber content, the morphology and mechanical properties, and the renewability, recyclability and sustainability of kenaf fiber reinforced polypropylene. At the end the list of application and future development of this advanced material. As for the conclusion, kenaf could be a good alternative fiber to be used with polypropylene, with more and more applications and prospect for impending progress.

Introduction

Lubrication and cooling are the most important functions of a fluid applied during a metal cutting operation. However, the type and degree of lubrication and the degree of cooling required for a particular metal removal process depend on various factors which include the type of operation, the properties of the cutting tool and workpiece material, and the speed, feed, and depth of cut selected. Conventional machining processes are associated with heat generation, tool wear, energy consumption, surface and subsurface defects of the workpiece including surface roughness, residual stresses etc. All these problems can be checked by providing proper lubrication to the machining zone during the machining process. The cutting fluid reduces coefficient of friction at the chip-tool interface as well as at the tool-workpiece interface. This in-turn results in reduction of resultant force by diminishing frictional forces at the two interfaces. At the same time, it also helps in removal of chips during machining and cooling down the cutting zone effectively. The most common and conventional method of the application of lubricant during machining is flooded lubrication technique in which the lubricant is allowed to impinge on the cutting zone in abundance. Flooded lubrication technique is associated with various economic and environmental issues. Abundant usage of lubricant increases manufacturing cost and causes dermatological and respiratory syndromes to the machinists. A large amount of fluid used in this technique is generally mixed with biocides to make it reusable. Biocides are detrimental to the environment. Disposing of cutting fluid is also a great ecological concern if it is non-biodegradable. That is why governmental rules are becoming stricter towards the use and disposal of cutting fluids. The best and ideal alternative is to perform dry machining where no harmful cutting fluid is used. However, dry machining is not feasible in most of the cases, especially in Al and heavy-duty machining. Another alternative is to use environmentally safe renewable cutting fluids. Nevertheless, the problem is that they can be used only after mixing with various additives. The additives are mixed in these oils to make them suitable for the use as cutting fluids. Several blends of such cutting fluids are available in the market. Initially, the share of such lubricants was very low in the worldwide lubricant market, but now, the growth is anticipated at a very high rate annually. There has been increased interest in the development of metal working fluids that can be derived from renewable resources. The most common renewable base oils used for the development of cutting fluid are synthesized esters received from a triglyceride of vegetable oil (e.g., rapeseed oil, palm oil) or animal fat. Renewable base oil, either natural or synthesized, required additives and the formation methodology as transesterification, hydrogenation etc. used to tailor the properties. These are to be carefully considered for the formation of a renewable metal working fluid.

Renewable Metal Working Fluids

Traditional non-renewable lubricants can be effectively replaced by the cutting fluids produced through renewable base stocks. In the modern era, industries are adopting measures for sustainable development by reducing the dependency on non-renewable natural resources. Therefore, the demand for renewable metal working fluids is increasing day by day because they are generally non-toxic, environment-friendly and readily biodegradable in nature along with having good lubricating properties. In some cases, renewable metal working fluids, having high affinity to the mating surfaces during machining, show better lubricating properties than that of the petroleum-based oils. These oils can be used as base oils in lubricants because they generally remain liquid at room temperature as well as they contain at least one ester as a functional group. Chemical properties of the base oil affect its successful application in machining process. Adsorption property of the oil makes it able to adsorb onto frictional surface and prevent their contact during machining processes. This property depends on interaction of functional groups of the oil with the surfaces. Properties which allow a lubricant to act as metal cutting fluid include its non-toxicity, biodegradability, high viscosity index, good lubricity (Mahadi *et al.*, 2017) and its ability to form a boundary lubricant through penetration into the mating surfaces during machining. By adding suitable additives, properties of a natural oil acting as base oil can be altered to make it suitable for acting as a lubricant in machining processes. There are three important factors on which the performance of a lubricant depends namely, base oil, additives and formulation methodology as shown in Fig. 1 below. Low thermo-oxidative stability is a major issue encountered during the use of renewable natural oils in metal cutting applications. Their stability can be improved either through esterification/transesterification process for modification of the carboxyl group or through the methods like selective hydrogenation, dimerization/oligomerization, formation of C–C and C–O bonds, metathesis or oxidation used for modifications of the fatty acid chain (Shashidhara and Jayaram, 2010).

Additives

Renewable oils, either natural or synthesized, cannot be used in their purest form (without additives) as metal cutting fluids because they lack various essential features. Performance of the oil is improved with the addition of proper additives in appropriate proportions. Additives affect the properties of tribofilms or boundary lubrication film significantly. This surface protection

Fig. 1 Formation of renewable metal working fluids.

film is developed between the mating surfaces by chemical changes on the surfaces, which are influenced by these additives. Anti-wear additives (AW), extreme pressure additives (EP), anti-oxidants (AO), emulsifying agents (EA), and biocides are the most commonly used additives.

Primary function of EP and AW additives is to protect the metal surface during rubbing. These additives react thermo-chemically with the heated metal surface and produce a protective film of easily sheared layers of sulphides, chlorides or phosphides. These layers are sheared off first during machining protecting the tool and machined surface. Some of the examples of AW additives are zinc dialkyldithiophosphates (ZDDP), S-[2-(acetamido) thiazol-1-yl] dialkyl dithiocarbamates, Palm oil methyl ester (POME), Dibutyl 3,5-di-*t*-butyl-hydroxy benzylphosphate (DBP) etc. The additives form polar head of the molecular layers, which are closely packed and arranged in a proper order to form the lubricating film. Extreme Pressure (EP) additives form layers of sulphides, chlorides or phosphates of iron through tribochemical reactions and protect the mating surfaces in EP conditions. Zinc-Dialkyl-Dithio-Phosphate (ZDDP) acts as EP additive. Butylated hydroxyl anisole (BHA), Butylated hydroxyl toluene (BHT), Mon-*tert*-butyl-hydroquinone (TBHQ), propyl gallate (PG) are those additives that act as chain-breaking antioxidants. Zincdithiophosphates (DTP), Dithiocarbamates (DTC) are the examples of peroxide decomposer antioxidants (Choudhury and Muaz, 2018). Environmentally safe nanoparticles, like TiO₂, CuO and ZnO are reportedly giving good results comparable to the conventional EP additives (Zainal *et al.*, 2018). Emulsifying agent (EA) is also an important additive for such applications. EA is mixed to develop stable renewable oil-in-water emulsion. Polyoxyethylene (20) sorbitan monopalmitate, polyoxyethylene (40) sorbitan tetraoleate, polyoxyethylene (20) sorbitan monostearate, Ethoxylated oleic acid ester are some common non-ionic EA. Biocides and anti-corrosive agents are to be added as additives according to the requirement. Ethanolamine is a good example of anti-corrosive agent as it helps in stabilizing the emulsion too. Biocides generally belong to family of triazine derivative (triclosan). They restrict the growth of bacteria and fungus in most of the renewable oils. Selection of the additives should be made intelligently and only those additives should be added which are necessary for a particular application (Choudhury and Muaz, 2018).

Properties of Renewable Metal Working Fluids (MWF)

Renewable MWF are now becoming the most important alternatives to traditional petroleum-based fluids because of their inherent qualities like possibility to achieve tailor-made properties, no toxicity, and excellent biodegradation. Organic compounds

containing ester linkage have good lubricating properties. An ester is a product of chemical reaction between alcohol and fatty acid. Presence of organic groups coming from alcohol and organic acid and the ester linkage of high bond energy incorporates excellent properties to the oil, including good response to additives. Various biopolymers, glycerol and gelatin were also tested in the application of metal working fluids. Renewable oils demonstrated similar or in some cases better machining performance than that of the conventional mineral oils. In some basic properties, most of the renewable oils are superior to mineral oils. As far as their application in machining is concerned, the most important property is the lubricity of the renewable oil. Boundary lubrication is the dominant lubrication mechanism in the vegetable oils because of high polarity of the base oil due to which strong interaction occurs between the fluid and the mating surfaces during machining. Presence of polar charge and oxygen containing functional group in the oils make these oils able to produce thick and stable lubricating layers on the interfaces (Choudhury and Muaz, 2018). Polar charge present in fatty acids of the oil draws the molecules of oil towards the metallic surfaces. These molecules do not flow out easily from the interacting surfaces. Oxygen-containing functional groups present in these oils also have an affinity towards metallic surfaces. The most basic component of a vegetable oil is a glycerol molecule. Triacylglycerides (triglycerides) are glycerol molecules consisting of three long-chain fatty acids. Hydroxyl groups are attached to the fatty acids through ester linkages. Long chains of fatty acids are polar in nature, which make them able to provide lubricant films of high strength. This film interacts strongly with metallic surfaces and reduces both friction and wear.

Renewable oils, in various aspects perform better than mineral oils because the viscosity, flash point, biodegradability and lubricity of renewable oils are higher while toxicity, friction and wear characteristics are lower than that of the mineral oils (Zainal *et al.*, 2018). High viscosity indices of vegetable oils make them applicable for a wide range of temperature by maintaining thick lubricating film even at high temperatures. In the purest form, renewable oils generally are more viscous than mineral oils. In most of the metal cutting applications, high viscosity is favorable because it provides a stable layer over the mating surfaces. However, the viscosity depends on temperature, pressure and film formation. Higher flash points of vegetable-based lubricants made them safer than mineral oils. Antiwear properties of these oils are also better than mineral oils as they can easily produce protective film over the contacting surfaces (Chandrakar and Suhane, 2014). However, these oils are inferior to mineral oils in terms of oxidation stability, thermal stability, corrosion protection etc. but can be modified by blending with suitable additives.

Classification of Renewable Metal Working Fluids

Renewable metal working fluids can be broadly classified as water-based or oil based fluids as shown in Fig. 2 below. Water based fluids can be further divided into emulsions and solutions. Emulsions can be produced through synthesized renewable oils or through natural vegetable oils after blending the oils with suitable emulsifiers. A large number of different vegetable oils namely, palm, coconut, olive, soy, neem, sunflower, castor, jojoba etc. can be used for the production of emulsions. These oils do not dissolve in the water but only get dispersed homogeneously producing emulsions. Water-based solution can be produced by using materials synthesized from renewable base fluids. Examples include glycerin and cellulose. Oil-based renewable metal working fluids can also be produced by using vegetable natural oil or by using synthesized esters. These esters are extracted from renewable resources that may be floral or faunal. In all the oils discussed so far, the base oil is extracted from a renewable resource and then it is modified as per the machining requirements. Compositions of the cutting fluids vary with the requirements. As an example, composition of emulsions required for light to heavy duty machining is illustrated in Table 1 below.

Selection of Cutting Fluid

Considerable efforts are necessarily to be made when selecting a right metal working fluid for machining practice. Choice of a cutting fluid is based on various factors including the properties of workpiece material, the type of machining operation, required output responses like tool life, surface finish, desired tolerance etc., along with economic and environmental concerns (Kelly and Cotterell, 2002). In the 1960s, the most important criterion was the price per gallon of the oil because it was believed that this have no significant influence on the manufacturing processes. In modern days, serious attention is generally paid towards selection of a proper fluid according to the requirements. Following criteria must be considered for selecting a suitable cutting fluid for a particular application:

- Lubricating and cooling ability.
- Operator safety.
- Renewability of the resources.
- Ease of disposal or recyclability.
- Low cost.

The most important criterion is the ability of the fluid to improve the machinability by generating desired shape, size, finish and accuracy on work material and extending the tool life. Next is the compatibility of the fluid in terms of its applicability to a wide range of work materials, anti-corrosion properties, resistance to microorganism growth and long life. Similarly, the fluid should be safe for operators' health and for the surrounding environment. In a nut shell, cheapest fluid must be selected based on

Fig. 2 Classification of renewable metal working fluid. Reproduced from Brinksmeier, E., Meyer, D., Huesmann-Cordes, A.G., Herrmann, C., 2015. Metalworking fluids – Mechanisms and performance. CIRP Annals – Manufacturing Technology 64 (2), 605–628. doi:10.1016/j.cirp.2015.05.003.

Table 1 Composition of cutting fluids (in wt.%) for different types of machining

	Base oil	Emulsifier	EP additives	Other additives
Light duty machining	83	15	0	2
Medium duty machining	70	15	10	5
Heavy duty machining	30	20	40	10

Note: Stephenson, D.A., Agapiou, J.S., 2016. Metal Cutting Theory and Practice. third ed. Boca Raton: CRC Press, Taylor and Francis Group.

operator safety, kindness to the machine, ease of disposal, the ability to perform the needed cutting (Sluhan, 1994). Different cutting fluids show a variety of diverse properties: some fluids provide only good cooling effect, some provide only good lubrication while some are good enough in demonstrating both of the two properties simultaneously. Economic issues related to the cutting fluids like the cost of recycling the fluid, the cost of fluid disposal are also to be considered. Moreover, environmental issues are becoming more important day by day. Nowadays, sustainable development is becoming the necessity where resources should be utilized keeping in mind the needs of the future generation. Sustainable development of manufacturing industries can be achieved through a modern manufacturing strategy known as green manufacturing by reducing the resource consumption, waste production, and pollution through proper design of product or process (Dixit *et al.*, 2012). Use of conventional metal working fluids can be effectively replaced with the fluids produced by utilizing renewable resources. Cutting fluids based on vegetable oils are the best alternatives to the conventional ones as they are non-toxic, environment-friendly and readily biodegradable in nature along with having good lubricating properties. As far as the properties of workpiece materials are concerned, the required properties of the cutting fluids vary widely. Cutting fluid used for machining a ductile material like Al should possess good cooling capacity while for a hard and difficult-to-cut material highly viscous fluids with good lubricating properties are required. Emulsifiable oils which are more advantageous than straight or compounded cutting oils in various aspects can be used for most heavy duty applications (El Baradie, 1996).

Application of Renewable MWF for Machining of Al

Ordinary cutting fluids used for machining of steels are not feasibly applicable for the machining of Aluminum and its alloys. Cutting fluids are to be modified to make them suitable for this special case. Therefore, special attention should be paid towards selection of the best suited fluid by considering following three important points (Kelly and Cotterell, 2002):

1. Rapid thermal expansion

Coefficient of thermal expansion of Al is very high as compared to iron and steel. During machining, when temperature of the workpiece increases, undesirably it expands rapidly in all directions. Therefore, cutting fluids with high heat dissipating ability are desirable.

2. Formation of hard Aluminum oxides

Temperature of the workpiece increases during machining. When heated metal is exposed to the oxygen, very hard Aluminum oxide films are developed. These films are responsible for reduction of tool life and deterioration of machined surface. Therefore, such cutting fluids are required, which have the ability to suppress the formation of Aluminum oxides.

3. Adhesive nature

Presence of significant amount of Silicon in an Al alloy makes it sticky in heated condition. As a result chip welding and built-up edge formation is promoted which is detrimental to the tool life and machined surface. Particular additives should be mixed with the lubricant to cope up with this problem.

Among all the three problems associated with the cutting of Aluminum, adhesion is the most detrimental. Adhesion is basically dependent on the presence of Si in an Al-alloy. As Al alloys are lightweight, they are used in large volumes in automotive industry to make the vehicles fuel-efficient. The automotive parts like engine and gear box are generally manufactured through casting operation. Ability of the Si to improve the castability and to make the final product more abrasive resistant made its addition into the alloy inevitable for complex castings (Coelho *et al.*, 1995). However, as far as machining of the cast parts are concerned, it shows detrimental effects by making the material adhesive. It is very important to consider its presence before starting work on it. Some researchers investigated the application of natural oils using MQL during machining of especially this type of Al-alloy. Although, MQL is emerging as an environment-friendly and promising technique for the application of metal cutting fluids, it has not been selected for the machining of Al alloys extensively (Filipovic and Stephenson, 2007). As compared to conventional machining, machining of Al through MQL is cheaper, environmentally safe by reducing the aerosol particles, and produces dry chips since the applied lubricant is fully burnt out at the machining zone. Itoigawa *et al.* (2006) investigated the effects of natural oil mixed with water and applied through MQL to the Aluminum silicon alloy (AlSi5), which is not easily machinable. Natural oil develops a boundary film on the tool face. This film is very weak and therefore it can only be beneficial in light cutting operation. It neither can restrict the adhesion of the work material to the tool nor provide good friction. Water mixed with oil plays an important role in MQL application to the Al-alloy. Water helps in providing proper lubrication by improving chemisorption and by sustaining film strength by cooling down the oil (Itoigawa *et al.*, 2006).

Davoodi and Tazehkandi (2014) applied vegetable oil while machining Aluminum alloy 5083 and tried to provide optimum cutting parameters that can be used to eliminate the usage of lubricant completely. However, the details about the oil used are not provided by the authors.

Sreejith (2008) investigated the effect of dry, flooded and MQL conditions on the machining of 6061 Al-alloy which has Mg and Si as major alloying elements. It was observed that the work material adhered to the tool at all faces and in all machining conditions. The adhesion was dependent on the amount of applied lubricant. However, adhered amount was lowest during flooded lubrication while highest during dry cutting. MQL reduced the adhesion as compared to dry cutting. The author suggested that it could further be reduced in the case of MQL by improving the tool geometry. Similar trend was found for cutting forces also and it was suggested that cutting fluid constituents should be investigated for further reduction of forces in MQL application. Surface roughness was observed to be reduced with the application of cutting fluid. Economic and environmental benefits associated with MQL make this technique more acceptable for machining (Sreejith, 2008).

Jatropha-based soluble cutting oil, a renewable metal working fluid, exhibits satisfactory performance during the machining of 7050-T7451 Aluminum alloy. Its performance was compared with other oils like canola (vegetable oil), semi synthetic (mineral oil), and synthetic (Jatropha ester) oils. The Al-alloy, having composition of 6.2% Zn–2.3% Cu–2.2% Mg and 0.2% Zr, is commonly used for the production of the components of aeronautical structures. The presence of esters, unsaturated aliphatic hydrocarbons (double-linkage), polycyclic/mono-replaceable aromatic hydrocarbons, CH₂ of long chain and linkages N–H along with sulphur (0.63694%) make them suitable for machining of Al-alloy. Absence or insignificant presence of phosphorous, chlorine and nitrosamines make the oil environmentally safe. The addition of extreme pressure (EP) additive containing Sulphur is necessary for an oil to act as good lubricant. However, its content should be below the allowed limit (<4%) set by ASTM D874. Significant reduction in cutting force and increment in tool life was observed when Jatropha based oil was applied. Very low cutting forces were observed. The fluid showed much better lubricating ability as compared to other oils like canola (vegetable oil), semi synthetic (mineral oil) or synthetic (Jatropha ester) oils by increasing the tool life tested at various feed rates. Foam generated by Jatropha based fluid was at the acceptably low level as compared to the canola-based oil. The renewable metal working fluids that have clusters of nitrogen and hydrogen (N–H) as in Jatropha vegetable-based oil are more suitable for machining of Al-alloy as compared to the fluids containing clusters of alcohol and CH₂ as in canola vegetable-based oil (Bork *et al.*, 2014).

The renewable metal working fluids should not be relied upon solely for the machining of Al-alloys, especially the alloys with high Silicon content. Other factors responsible for improving the machinability should also be considered simultaneously. For example, during reaming of an Al-alloy (AlSi12), acceptable results were obtained when the fluid consisting of fatty alcohol was applied through minimum quantity lubrication technique and the tool with PVD coating was used (Lugscheider *et al.*, 1997).

Application of MWF for Heavy Duty Machining

Heavy-duty machining demands cutting fluids capable of providing heavy-duty lubrication and high cooling. Moreover, as the fluids are to be impinged at high pressure and flow rates, they must have low foaming characteristics. Creep-feed grinding and hard turning are the examples of heavy-duty machining that requires such type of cutting fluids, which have the combination of all the three properties (Sluhan, 1994). Heavy-duty machining operations require cutting fluids that exhibit very good lubricating property along with cooling ability at heavy loads. Emulsions exhibit both lubricity as well as cooling ability due to the presence of soluble oil and water respectively (Muaz and Choudhury, 2019). However, the oil film strength or hydrodynamic lubrication potential is reduced due to the presence of water. Therefore, in order to make emulsions suitable for heavy-duty applications, lubricant additives are added. Boundary lubricants such as lard oil, esters, amides, soaps, and rapeseed oil can be used as boundary lubricants. Similarly, chlorinated, sulfurized, and phosphorus-based extreme-pressure additives are necessarily be added to improve the load carrying capacity (Childers, 2006). Renewable metal working fluids like vegetable oils cannot perform satisfactorily in their original form. However, their properties can be improved by blending the base oil with suitable additives. EP soluble oils, commonly known as heavy-duty soluble oils, are the best alternatives as they can satisfy both the requirements in most of the cases. Conventional EP soluble oils can be replaced effectively by renewable metal working fluids by modifying vegetable oils base blended with EP additives in large amount (about 40% by weight). EP additives improve the load carrying performance of the base oil. Most of the EP additives contain chlorine, sulphur or phosphorus.

Cooling capability of renewable metal working fluid can be enhanced by blending emulsifiers into the base oil. Emulsifiers make it possible to form an oil-in-water emulsion containing a dispersion of oil droplets in a continuous phase of water. Chlorinated paraffins or sulfurized fat emulsifiers are utilized for producing heavy-duty soluble oils (El Baradie, 1996). As the cooling ability of the fluid is to be enhanced significantly for heavy-duty applications, about 20% by weight of emulsifiers are to be blended with 30% of the base oil as shown in Table 1. For low speed heavy-duty machining operations such as threading, broaching, tapping gear hobbing, etc. such oils are required that can chemically react with machining surface at high machining pressures and temperatures (Shokrani *et al.*, 2012).

Avila and Abrao (2001) performed rough turning of hardened AISI 4340 steel (49 HRC) at a depth of cut of 2 mm by mixed alumina ($\text{Al}_2\text{O}_3 + \text{TiC}$) tool. Three cutting fluids, namely fluid A (emulsion without mineral oil), fluid B (synthetic) and fluid C (emulsion containing mineral oil) were applied and compared with dry cutting. Fluid A does not contain any mineral oil but contains some grease into it. For the heavy-duty machining, fluid A containing no mineral oil provided best results while fluid B containing mineral oil exhibits worst results as far as tool life was concerned (Avila and Abrao, 2001).

Some patented renewable metal working fluids are available in the market that are suitable for heavy duty machining of most ferrous alloys. These fluids can be applied during stamping, drawing, milling, turning, drilling, grinding, honing, broaching, thread cutting, and tapping operations. Examples of such fluids include Bio-HeavyTM S Cut which is formulated by highly viscous agricultural vegetable oils, high oleic base stocks (HOBS), blended with active sulphur extreme pressure additives. The fluid provides wetting and oiliness of tool, extreme pressure and antiwear properties with additional load carrying capacity.

In some severe heavy-duty machining conditions, if a lubricant fails to penetrate the machining zone, application of the cutting fluid with compressed gas is also an alternate method.

Future Trends

Heavy-duty applications demand high concentration of additives that are generally not good for environment. Environmentally benign alternate additives, like nanoparticles, are to be explored and their use to be established for the machining operations.

Rigorous multi-objective optimization of the parameters of the renewable metal working fluids must be performed for selecting and implementing the best-suited fluids to a particular machining process on the shop floor.

Emulsifying agents are also not recommended to be used in the fluids because these elements are hazardous to human health and detrimental to the environment. Research must be carried out in the direction of exploring the possibilities of emulsion development without mixing emulsifying agents. A very little work has been reported in this direction e.g., ultrasonic atomization, but must be explored further for renewable MWF.

Conclusion

Renewable metal working fluids have shown great ability to work satisfactorily in Al as well as in heavy-duty machining applications. Dependency on non-renewable resources can be reduced by replacing the mineral oils with renewable oils in production

of metal working fluids. A cutting fluid capable of performing well in a particular application should be selected judiciously based on the requirements and the properties of the fluids. The fluid properties can be tailored according to the requirement.

Introduction

The dawn of proliferating production and consumption of products has brought along with it increased exploitation of natural resources and waste generation, which conspicuously reflects an increase in the rate of damage done to the environment. Apart from rapid depletion of fossil fuels, development has left behind pollution, deforestation, loss of biodiversity and climate change. A considerable contribution to environmental damage is inflicted by the global stock of plastics. While the utility and production of plastics outclasses most other material systems, the exhaustive investment of fossil resources for their synthesis and the aftermath associated with their disposal has rendered these multiutility materials subject to comprehensive environmental scrutiny. In the first ever global analysis of commercial plastics, [Geyer et al. \(2017\)](#) estimated a total production of 8300 million metric tons (MT) of virgin plastics by 2017, and generation of plastic waste amounting to 6300 million MT by 2015. Of the plastic waste, it was estimated that 9% was recycled, 12% incinerated and a perturbing 79% was accumulated in landfills and other dumping sites such as oceans. Following this, 12,000 million MT of plastic waste is expected to stockpile in natural sites by 2050. In 2015, [Jambeck et al. \(2015\)](#) calculated that out of 275 million MT of plastic wastes generated in 192 tropical countries in 2010, 4.8–12.7 million MT eventually found its way into the ocean. While this might not appear significant compared to the aforementioned global statistics, such annual influx of plastic debris has the potential to devastate the marine ecosystems.

Sought as a solution to the environmental crisis effectuated by commercial fossil-based plastics, bioplastics incorporate plastics developed from renewable resources as well as those which are biodegradable. While biodegradability is an indispensable requirement for any eco-friendly plastic, those obtained from renewable feedstock do not always meet it ([Fig. 1](#)). Biobased plastics such as Nylon 11 derived from 11-aminoundecanoic acid present in castor oil and polyethylene synthesized from bioethanol present in sugarcane and corn for instance are not biodegradable ([Deanin, 1978](#); [Tokiwa et al., 2009](#); [Kuo et al., 2006](#)). Likewise, it is also not necessary for a biodegradable plastic to have biobased origins. Essentially biodegradation of any plastic is a complex phenomenon depending on its molecular weight, hydrophobicity, and the nature of additives present in the matrix and has been addressed in detail later in this text. Thus, bioplastic is a general term associated with any plastic that has at least one eco-friendly facet.

It is necessary for the ensuing discussions that the term sustainable development is not misapprehended. It accounts for evolution that answers to the requirements of the industry and the economy without inflicting damage upon the environment. For instance, an extremely eco-friendly material with inferior properties that do not allow it to settle into industrial applications is not sustainable. Naturally, no material or process can be perfect with respect to this idea of development. However, the closer they get to it, the more they are preferred. Any material affects the environment in several stages throughout its life span. While finding potential renewable materials for development of plastics and compostability of existing commercial plastics have been meticulously investigated and discussed in literature, the other aspects of the life-cycle of a plastic such as requirement and discharge of toxic effluents and energy influx during the extraction of raw materials, production of plastic and disposal must also be scrutinized to assess the overall impact on the environment. It is further imperative to consider these factors because the damage done to the environment is not limited to waste accumulation and depletion of fossil reserves, rather pollution, global warming and depletion of biodiversity are also pressing concerns. Along these lines, considering biobased or biodegradable plastics as the goal of sustainable development is biased and flawed. A perfect bioplastic, while catering to the industrial requirements it is designed for, must therefore cast the minimum deleterious impact on the environment through its entire life-cycle.

A comprehensive analysis of the sustainability concerns associated with the existing bioplastics is crucial for identification of research gaps and subsequent development of methods for eliminating them. In this article, the possible detrimental impacts of bioplastics on the environment and the established sustainability concerns associated with these have been delineated. The most common commercial bioplastics were analyzed with respect to their life-cycle, and product-based case studies were provided.

Quantification of Sustainability

Consider the life cycle of a plastic product ([Fig. 2](#)). The consumption of fossil fuels is not limited to extraction of raw materials, rather the energy consumed at each stage of the life cycle is either directly or indirectly derived from fossil resources. Moreover, release of emissions and effluents as well as consumption of water also occurs at each stage. The overall environmental impact of a bioplastic must depend on total resources (fossil, water and land) consumed, the total emissions and effluents released into the environment as well as the toxicity of these. In a theoretical statistical analysis, minute components of the product life cycle such as

¹These authors contributed equally.

the amount of water used in irrigation of the crops which yield the monomer for the plastic are difficult to include, since a broad analysis taking into account all such components of the study requires collection and analysis of an enormous amount of data. The small environmental impacts associated with all such components of the life cycle cumulatively generate a significant environmental impact. Thus, in order to develop a complete picture, databases as well as pre-defined standardized mathematical approaches are required to obtain reliable and relevant conclusions. For this reason several sustainability measurement methods have been developed. The most common methods, which assign quantitative indexes to the sustainability potential of bioplastics and therefore make the associated environmental impacts easy to visualize have been discussed as follows.

Sustainability Metrics

Over years of environmental concerns, several methods and approaches have been developed to quantify the potential of processes and products for sustainable development. One such approach is the evaluation of “Ecological Footprint” developed by Wackernagel and Rees (1998), which is an approximation of the ecological capacity necessary to support a population or economy based on statistics of consumption of natural resources and waste generation by a pre-defined unit. Subsequently comparisons are made to juxtapose the required ecological capital with the available natural capital to evaluate the gap between the unit functions and sustainability. Along similar lines the World Business Council for Sustainable development (WBCSD) has developed approaches to amalgamate general business practises with sustainability and advocates accelerated transition to an ecologically stable world (Sandberg *et al.*, 2010; Lehn, 1998; World Business Council for Sustainable Development WBCSD, 2001). Other common approaches include Circles of Sustainability (James, 2014), Environmental Sustainability Index (ESI) (Esty *et al.*, 2005), Environmental Impact Assessment (EIA) and Life Cycle Sustainability Assessment (LCSA). The latter two approaches have been used specifically for analysis of products and manufacturing methodologies, especially in plastics, and have henceforth been described.

Environmental impact assessment (EIA)

Environmental impact assessment constitutes one of the oldest tools for evaluation of the environmental footprint of a process, project, material, policy or product. While several similar procedures have existed for years, the most standard and widely accepted EIA process emerged from the US National Environmental Policy Act 1969 (NEPA), and has been expansively used for identification, prediction and mitigation of ecological damage associated with development propositions. It is performed in sequential stages including screening, scoping, baseline data collection, impact prediction, impact assessment, mitigation, formulation of Environmental Impact Statement (EIS), subsequent review and follow-up. While EIA forms an effective utility for analysis of potential damage by plastic processing methodologies such as plastic injection molding (Pun *et al.*, 2003), and lays the framework for finding alternative approaches, there are numerous limitations associated with the formal and informal review generated post EIA, along with the dispute on fulfillment of its objectives specified in NEPA (Petts, 2009). The approach has received criticism for its limited scope and effect on the final decisions associated with proposals (Jay *et al.*, 2007). For such reasons, it is not preferred for the smaller, more specific domains.

Life cycle sustainability assessment (LCSA)

LCSA constitutes a comprehensive sustainability assessment, involving a thoroughgoing analysis of environmental, economic and socio-economic impacts of a product throughout its life cycle (Fig 3):

The concept of using the three assessment techniques i.e., LCA, LCC and S-LCA together was first proposed by Kloeppfer (2008) and is now endorsed by United Nations Environment Program (UNEP) and several other international organizations working towards sustainable development. Since sustainable development is an amalgamation of environmental, social and economic viability in development, simultaneous assessment of all the aspects of the unit under consideration are important. For example, an eco-friendly product that is either very expensive or does not meet the requirements of the social backdrop will not broadly supplant its less eco-friendly alternative.

Fig. 3 The concept of sustainable development.

Life cycle assessment (LCA)

Life Cycle Assessment is the most broadly accepted method for quantifying the environmental impacts associated with products. The need for LCA stems from the requirement to consider the entire spectrum of environmental impacts that are connected to the life cycle of any entity, which is not only lacking in other assessment routes, but also provides an all-encompassing assessment which generates the overall perspective necessary to compare between alternatives and select the eco-friendliest option. LCA is performed either by considering the complete life cycle which includes the extraction and processing of raw materials, manufacturing, transportation and distribution, use reuse and maintenance, recycling and final disposal, in which case it is called a cradle to grave assessment, or by evaluating only the part of life cycle involving production. The latter is called cradle to gate assessment and is usually used mostly by firms producing the product. The input and output of energy and materials at each stage of product life is considered and analyzed. Thereafter, indices are provided to estimate quantitatively the overall damage fostered in various aspects, each of which represents a facet of pressing environmental concerns. A life cycle study can either be focused on assessment of an individual product or utilize the collected data to compare between two products or processes, in which case it referred to as comparative LCA. In accordance with the international standards accepted for LCA (ISO 14040 and ISO 14044), it is performed in four steps: goal and scope definition, life cycle inventory, life cycle impact assessment and interpretation. These have been described briefly as follows:

- (1) *Goal and Scope Definition*: A life cycle study is typically application specific and requires a framework for distinguishing and filtrating relevant data from the countless data elements available. For quantification, data must be limited to a functional unit and the circumference of the aspects related with the product or process to be considered must be established. Thus, in this step, the following factors are defined to build the framework for the subsequent study:
 - (a) The requirement and purpose of the study (or the 'Goal') is defined, which makes the overall study concise and compendious.
 - (b) System boundaries, such as technical and geographic limits on the subject as well time frame of analysis are specified. The systems to be analyzed in the study are also delimited.
 - (c) Reference function (or Functional unit), which provides the baseline for calculation of input and output variables through the life and the ensuing quantification of associated impact. For example, in a study of polyethylene bags, a functional unit could be 100 bags manufactured in a particular region.
 - (d) The various assumptions associated with the study are demarcated, along with a description of the groups the study will be addressed to (following the earlier example, the study could be addressed to academic, technical, and marketing personnel, along with general public or legislative bodies).
 - (e) The standardized methods implemented in the study, and the specific impacts to be addressed in the study, along with the weight assigned to each specific impact studied is defined.
 - (f) If the study is intended for public and academic reference, it is necessary to specify the need of a peer review.
- (2) *Life Cycle Impact Assessment*: This step involves collection, description and verification of relevant data, which includes emission and resource consumption values, along with intermediate chemicals and other unit processes which are likely to yield an environmental impact. Data acquired can be of two types, based on its origin:
 - (a) Primary data includes data acquired directly from its source, such as in annual government or company reports, interviews and other official articles. This data is considered more relevant and reliable from a scientific perspective.
 - (b) Secondary data is acquired from commercial and public LCA databases such as Ecoinvent and European Life Cycle Database, and from previous published LCA studies. A very common approach towards contemporary life cycle studies is use of LCA software database, of which two very broadly used softwares include SimaPro (PRé Sustainability) and GaBi (Thinkstep). A few other LCA softwares such as OpenLCA (GreenDelta) and Umberto (Ifu Hamburg) are also used.

Based on the choice of processes to be included in the study, the product system is modeled and fed the amassed data. The step produces a Life Cycle Inventory (LCI), which contains organized information related to the various input and output processes between the product system and the environment.

- (3) *Life Cycle Impact Assessment (LCIA)*: In this step, the raw data accumulated in LCI is used to evaluate the quantified contribution of the product or process in consideration on impact categories, which represent environmental issues of concern such as global warming, eutrophication, fossil depletion etc. It is concluded in five stages: Selection, classification, characterization, normalization and grouping. Relevant impact categories are chosen based on the assumptions taken, the goal and scope of the study, as well as based on the environmental impacts that need to be studied in reference to the subject. Post characterization, the impact categories are normalized and assigned weights based on which environmental aspect is considered more critical with respect to the application being studied.
- (4) *Interpretation*: This step involves analysis of the LCIA results to provide meaningful and comprehensible conclusions. Sensitivity and uncertainty analysis are performed to check the reliability of the results of the study, based on which, it is inferred whether the goal and scope of the study have been met.

Life cycle costing (LCC)

Life Cycle Costing (LCC) is an important economic evaluation employed in the selection of alternatives that impact both pending and future costs. It combines and thereafter assess the costs related to the product over the span of its life i.e., production, use,

reuse, maintenance and disposal (Andrews, 2009). It is driven by the fact that the purchase price of the product does not reflect the complete picture of all the costs that are caused by the product and thus takes into account all costs occurring during a product's life cycle irrespective of the party bearing them. Conventional LCC has existed since a long time but is quite different from the concept of environmental LCC. It is performed to back the policy making process in the financial division to predict the preliminary investment and subsidiary monetary flows on maintenance, disposal, etc., (Spierling *et al.*, 2018). The focus of conventional LCC is on net savings, benefits or savings-to-investment ratio (Kloepffer, 2008). Moreover, since the conventional LCC lacks compatibility with LCA (Herrmann, 2009), therefore the LCI of both LCC and LCA are kept same and the boundary conditions are kept equivalent so as to ensure the compatibility between two in order to carry out a meaningful analysis. In case of biobased plastics, conventional LCC can be of interest especially when it comes to new production equipment.

Social life cycle assessment (S-LCA)

This technique is a collection of chronological procedures very similar to LCA which allow evaluation of the social impacts of a product through its life-cycle. Analogous to how LCC establishes the economic feasibility of a product or process, SLCA discusses the social feasibility based on the evaluated social impacts. It is based on the ISO 14040 framework and is related to assessment of impacts that directly affect the stakeholders, the social circle the product or process is addressed to and provided by.

Drawbacks

LCA constitutes one of the very few methods available for identification, quantification and analysis of sustainability issues associated with bioplastics. It is therefore very necessary that the results obtained at the end of an LCA study are inclusive of all the

$$LCSA = LCA + LCC + SLCA$$

possible environmental impacts of the bioplastic under consideration. However, in most LCA studies conducted, only few impact categories are considered, due to which they fail to provide a wholesome picture. There are two very discernible reasons behind this: the LCA methodology is complicated, which makes it difficult to analyze a plastic's potential for each impact category and the requirement of an enormous amount of data to ensure fair and accurate results in a study. Uncertainty in data is a major drawback of the LCA method, due to which most LCA studies rely on assumptions, which may or may not materialize in all real-life situations. The case study on sandwich composite panels discussed later exemplifies how unavailability of relevant data mandates assumptions which might make the data unreliable or case-specific. Thus, a requirement for improvement in the quality as well as the quantity of data available on databases is felt.

Another major drawback in LCA is the lack of standardization. For instance, if two bioplastics, each of which has been studied via LCA individually need to be compared, the previous studies cannot be used to draw comparison, since it is unlikely that the studies will be based on the same functional unit, or will have the same system boundaries. For any application specific analysis, a fresh LCA study is required. This makes comprehensive evaluation of bioplastics a resource-intensive process, which is a potential reason behind the lack of sufficient LCA studies. Due to the structure of LCA method, the results obtained are usually influenced by the nature of assumptions and the application, and thus cannot be generalized.

Biodegradability

While the global bioplastic production capacity is expected to wax from 2.05 million MT in 2017 to 2.44 million MT in 2022, biobased non-biodegradable plastics such as biobased polyethylene, biobased polyethylene terephthalate, and biobased polyamide currently constitute 56% (1.2 million MT) of global biobased production capacity (European Bioplastics, 2017). The precipitous rise in the aggregate Municipal Solid Wastes (MSW) due to plastics has compelled many governments to impose legislation to stem the plastic waste generation. Driven by such crucial requirement for waste management, and since it is the eco-friendliest solution to the end of life for plastics, biodegradability has been studied extensively and mandates special emphasis with respect to sustainability concerns. Composting is a special case of biodegradation. While biodegradation refers to the process of decomposition of plastic to CO₂, H₂O, CH₄ or elemental carbon, which can occur in soil or water in the presence of relevant enzymes, composting refers to biodegradation in an environment of decaying organic matter. Thus, every compostable plastic is biodegradable, however biodegradable plastics may or may not be compostable. For a plastic to be compostable, the following criterion should be met, in reference to the nature of its degradation (Rujnić-Sokele and Pilipović, 2017):

- The product must be composed of a minimum of 50% organic matter and should not contain heavy metal content beyond a certain allowable limit.
- The product must disintegrate to particles not visible to naked eye (< 2 mm in diameter) within 12 weeks and must biodegrade by at least 90% within 6 months in controlled composting conditions.
- Upon degradation, the plastic should not release toxins or materials which cast a detrimental effect upon the ecosystem of soil i.e., the residual compost should be non-toxic in nature (Fig. 4).

Fig. 4 Global production capacities of bioplastics in 2017. Adopted from European Bioplastics, 2017 Bioplastics: Facts and figures. Berlin. Available at: <https://www.european-bioplastics.org/market/>.

In general, fragmentation of plastics in natural environments such as soil and marine follows exceedingly slow kinetics and is projected to take centuries to exhibit any significant corrosion. Following decades of development in this sphere, the natural degradation procedures available now for plastics are not limited to soil composting under readily available environments. Rather several combinations of microorganisms and tailored environments for catalysing their activity, man-made enzymes and materials to effect deterioration etc. have been formulated. Developed bioplastics with augmented rate of natural degradation are now broadly used for manufacturing medical implants, carrier and waste bags, disposable cutlery, flexible films as well as rigid containers and bottles, diapers, tyres, mulch films and multitudinous other commonplace commodities (Rujnić-Sokele and Pilipović, 2017). Although there are sustainability concerns associated with degradable plastics, biodegradation still has the potential to develop into a solution to several environmental concerns. In order to develop biodegradable plastics with few to no concomitant sustainability issues, it is essential to understand the mechanism and methodologies of biodegradation.

Routes to Environmental Degradation of Plastics

Environmental degradation of plastics is a combination of several degradation mechanisms functioning simultaneously and consecutively. Prior to molecular degradation, corrosion and subsequent weakening of material is essential, which is contributed by a combination of mechanical, chemical, thermal and other abiotic factors operative in the outdoor environment. Usually these factors initiate and sometimes accelerate the degradation process.

Degradation by microbial communities

Polymeric materials have been shown to degrade in several natural and specifically defined artificial environments in the presence of microorganisms. However, soil is the most suitable environment for biodegradation, owing to the diversity of microbial communities that exist therein due to factors favouring survival. The microorganisms capable of degrading specific plastics are many and the nature and extent of degradation is also defined by ambient temperature and availability of free oxygen (Nishide *et al.*, 1999). Suyama *et al.* identified and isolated 39 morphologically different species of soil bacteria that could degrade poly(β -hydroxyalkanoate), poly(ϵ -caprolactone), poly(hexamethylene carbonate), and poly(tetramethylene succinate) (Suyama *et al.*, 1998). Biodegradation by microorganisms is a complex process, which follows three distinctive steps. An elaborate discussion of these has been provided by Lucas *et al.* (2008), and the stages have been very briefly summarized as follows:

Biodeterioration

It is a surface-level degradation which alters the physical, mechanical and chemical properties of the plastic and prepares it for ensuing break-down. This kind of degradation is usually an outcome of a combination biotic and aforementioned abiotic factors. From the perspective of microbial activity, there are several biotic mechanisms associated with this stage:

- Microorganisms secrete a complex amalgam of polysaccharides, proteins and similar polymeric substances, which allows them to adhere to the surface of the plastic. This material not only protects the microbes against unfavorable conditions, but also weakens the plastic in general by percolating through the pores in the plastic and converting them to cracks.
- The extracellular polymers secreted by microbes provide a medium for exchanges between hydrophilic and hydrophobic phases. This allows for easy permeation of bacterium into the plastic. It is also estimated that such secretions favor accumulation of atmospheric pollutants and provides favorable conditions to growth of microorganisms, which in turn accelerates the deterioration process.

- In thermoplastics, biodeterioration can either effect the bulk or the surface of the plastic. Bulk deterioration is usually dominated by abiotic factors such as ambient radiation and eroding compounds such as acid, bases, radicals etc. This naturally depends on the chemical characteristics of the plastic such as solubility and chemical resistance. Bulk deterioration results in disintegration of large chunks of plastic and cleavage of bonds, which effects reduction in the molecular mass. Surface deterioration is governed by enzymes secreted by microorganisms, which only cause loss of material and do not affect the plastic on a molecular level. Enzymes are not capable of producing bulk deterioration due to their inability to penetrate the polymer matrix, which is also why polymer molecules stay intact in surface deterioration.
- Certain species of bacterium, such as chemolithotrophic bacteria secrete inorganic acids and elements such as sulfur, hydrogen sulfide, ammonia and nitrates as sources of ions, electrons and energy. Likewise, chemoorganotrophic bacteria produce organic acids such as oxalic acid, fumaric acid etc. Such secretions can either react with and subsequently corrode the plastic or release cations which form stable organometallic complexes, thereby oxidizing the plastic. While each microbial community utilizes different secretions and mechanisms for biodeterioration, enzymatic action mostly only affects the surfaces exposed to them.

Biofragmentation

Cell membranes are impermeable to polymer molecules because of their large structure. Thus, prior to ingestion of molecules, they are fragmented to constituting monomers and oligomers. Akin to biotic biodeterioration, microbes employ different mechanisms for cleavage of bonds in polymer ranging from secretion of enzymes which reduce the activation energy of molecules and make them susceptible to chemical reactions causing bond rupture to generation of free radicals. The chemical aspects of the process are diverse and hence have not been covered in this text.

Assimilation

It occurs inside the cell and can be conveniently considered as the last catabolic stage of plastic digestion. The end products of biofragmentation are transported inside the microbial cell by membrane carriers and are subjected to catabolism. Disintegration of molecules into atoms yields the necessary nutrients required for the cell and produces Adenosine Triphosphate (ATP), which provides the energy for cellular metabolism and reproduction. Although some monomer and oligomer molecules obtained post fragmentation cannot permeate the cell membrane, they undergo bio-transformation reactions and subsequently assimilate inside the cell.

Factors Affecting Biodegradability of Plastics

During natural degradation of plastics, ambient conditions such as temperature, the amount of moisture, light and oxygen present as well as the pH of the soil or compost effect the rate and extent of degradation (Emadian *et al.*, 2017). Some of these abiotic factors and their contribution in biodegradation have been discussed in Table 1. Since biodegradation involves chemical interactions between the plastic and microbial interface at every step, the molecular characteristics of plastics have a significant impact on the viability and kinetics of enzymatic reactions, which in turn influence the rate and potential for biodegradation. Certain modifications in the composition, such as including additives containing high concentration of soluble sugar might enhance the biodegradability of the plastic (Emadian *et al.*, 2017). Thus, in order to design bioplastics with high biodegradability, it is necessary to have a comprehensive understanding of the factors that affect biodegradability. Andradý (2007) discussed the various factors which have been shown to affect biodegradability of synthetic and biobased plastics. Molecular characteristics which more prominently effect biodegradability have been summarized as follows:

Molecular weight

Molecular weight of a polymer molecule is a function of chain length and degree of polymerization, both of which have been shown to affect biodegradability. Earlier studies conducted on polyethylene established that biodegradation becomes negligible above a molecular weight of 4000 (Jen-hou, 1961). Later a more direct relationship was established in evaluation of degradation of polycaprolactone films of different molecular weights using the mold *P. Pullans* by Fields *et al.* (1974). The behavior of polycaprolactone was evidently similar to polyethylene, in that the degradation became negligible above a molecular weight of 15,000. A very sharp decline in the weight of plastic film recovered after 3 weeks in mold inoculated medium was observed in grades with molecular weight increasing from 1000 to 5000, post which it was concluded that degradation was directly proportional to low molecular weight.

Rivard *et al.* (1995) studied the effect of ester group chain length and the degree of substitution on anaerobic microbial digestion of starch esters including acetate, propionate, butyrate, valerate and hexanoate groups. A sigmoidal decrease in biodegradability of starch esters was observed upon increasing the chain length as well as degree of acetylation. It was also concluded that for maintaining a high biodegradation potential, with an increase in chain length, the degree of substitution should be decreased, which was generalized for natural polymers.

Chemical structure

The enzymes released by microorganisms react with the relevant functional groups to cause cleavage of polymer bonds. Generally, a plastic is acted upon by a colony of different microorganisms, each of which release different enzymes which collectively

Table 1 Types and mechanisms for abiotic degradation of plastics

Degradation type	Mechanism
Catalytic degradation	Catalysts such as zeolites, non-zeolites, platinum-cobalt and platinum molybdenum supported by SiO ₂ , transition metal catalysts supported by Al ₂ O ₃ etc., which are present or artificially added in the soil or other degradation environments are helpful in initiation or propagation of degradation. These catalysts reduce the temperature required for degradation, improve the quality of residues left post-degradation and increase selectivity for the product under consideration. In the initiation step, carbon-carbon bonds are cleaved to form free radical, which then leads to a chain propagation, where the hydrocarbon free radicals are converted to lower hydrocarbons. Thereafter disproportionation or recombination of free radicals then terminates the propagation step.
Ozone-induced degradation	Traces of ozone present in the atmosphere are known to increase the rate of polymer ageing. Ozone attacks the unsaturation present in the plastic and forms an ozone-olefin adduct known as primary ozonoid, which subsequently cleaves into carbonyl oxide and carbonyl compounds. The electron deficient carbonyl oxide is subsequently attacked by oxy-anion.
Mechanochemical degradation	This occurs due to existing mechanical stress, or due to exposure to ultrasonic radiation. The mechanical stress or the ultrasonic radiation (if the polymer is present as a solution) causes breakage of polymer chains into free radicals. These free radicals are generated by tearing of polymer chains, which generates fragments of chain carrying the free radical, thereby reducing the molecular weight. If oxygen is present in the degradation environment, then the free radicals are converted to peroxy radicals. This further leads to chain propagation. However, it must be noted that the cleavage discussed in this degradation occurs only in the amorphous regions present in between the crystalline regions.
Photo-oxidative degradation	Near UV radiation (290–400 nm) are responsible for degradation of plastics exposed to sunlight. The plastic undergoes loss of mechanical properties, yellowing and changes in molecular weight. At any given ambient condition, the rate of degradation increases with the incoming flux of solar radiation. The plastic absorbs UV light, which generates free radicals. In the propagation step, hydroperoxide radicals are generated, which cause backbone degradation, followed by beta scission. The backbone degradation follows either the Norrish Type I or the Norrish Type II mechanism. Subsequently in the termination step, the free radicals combine to form inert products.
Thermal degradation	While photo-oxidative degradation affects only the surface of the plastic, thermal degradation affects the bulk of the plastic. Usually either of Chain-end degradation or Random degradation mechanisms follow the application of heat, resulting cleavage of polymer chains: Chain-end mechanism initiates at terminal monomer unit in the chain and the monomers are stripped off the polymer chain one by one. In random degradation mechanism, the polymer randomly tears into two smaller molecules. Usually, both the reactions contribute in chain initiation step. However, the chain propagation step follows chain-end mechanism. The termination step follows either radical disproportionation or radical coupling reaction.

Note: Based on Singh, B., Sharma, N., 2008. Mechanistic implications of plastic degradation. *Polymer Degradation and Stability* 93 (3), 561–584

complete the many enzymatic steps involved in the degradation. A complex chemical structure with a large number of similar functional groups must require high stoichiometric amounts of enzymes, and those with many different functional groups must require many different enzymes for reaction and subsequent cleavage. Therefore, plastics with complex chemical structures usually form poor substrates for biodegradation (Andrady, 2007). This was experimentally observed in the biodegradation of dialdehyde starch and dialdehyde inulin (Van der Zee *et al.*, 1995). A higher degree of oxidation in both the polymers resulted in a lower rate of degradation. It was also observed that the oxidized grades of starch and inulin adopted different molecular conformations, which further altered their susceptibility to microbial attack.

Interaction with water

Microbial degradation involves enzymatic interaction on the plastic-microbial interface. The enzymes released by microorganisms sometimes require water a solvent medium. A hydrophobic plastic might restrict microbial growth on its surface (Fig. 5), which is manifested in higher biodegradability exhibited by water soluble polymers such as polyethers, PAA (polyacrylic acid), and PVA (polyvinyl alcohol) when compared with the water-insoluble polymers (Andrady, 2007). Likewise, in a study investigating the biodegradation of polyethylene (Karlsson *et al.*, 1988), which is hydrophobic in nature, it was observed that using a surfactant along with polyethylene enhanced its biodegradability. It was thus concluded that hydrophilic polymers exhibit increased accessibility for microorganisms. Presence of functional groups such as carbonyl can also increase the accessibility, and hence the biodegradability of the plastic (Andrady, 2007; Karlsson *et al.*, 1988).

Crystallinity

Crystallinity is known to hinder microbial degradation of plastics. A study conducted on the biodegradation of Polycaprolactone (Benedict *et al.*, 1983) suggested that crystallinity inhibited the fungal degradation of the plastic. In an analysis of degradation of Polycaprolactone by Cook *et al.* (1981), it was observed that the bacteria exhibited preferential degradation of amorphous plastic. In another study on the biodegradation of Poly(3-hydroxybutyrate) (Nishida and Tokiwa, 1993), it was similarly observed that occurrence of crystallinity suppressed biodegradation in PHB samples. The bacteria used in the inoculum preferentially colonization in and degraded the amorphous sites created in samples, whereas the crystalline sheets were left undegraded. This could be

Fig. 5 Bacterial interaction with hydrophobic polymers.

due to easy penetration of microbial enzymes in the less ordered amorphous plastic, which allows for homogenous enzymatic action. Since the microorganism itself feeds on the plastic being degraded, higher degradation in an amorphous plastic must release sufficient energy for more organisms to feed on and thus becomes a preferential colonization site. This in turn further increases the enzymatic action in the region and must increase the rate of degradation, much like a chain reaction (Nishida and Tokiwa, 1993).

General Concerns: Biodegradable Plastics and Biodegradability

Driven by the most common misconceptions about biodegradable plastics, which roughly equate the biodegradability of plastics to that of general organic matter, they are frequently sought as a solution to the problem of plastic littering and landfills. In reality however, biodegradable plastics degrade in very specific conditions, and these conditions must be provided as the end of life scenario in order to reap the advantage of biodegradability at all. For example, PLA is highly biodegradable in soil and compost, but is almost non-biodegradable, when placed in a marine environment (Haider *et al.*, 2019). In such a situation, PLA that ends up in the oceans forms marine debris. Most studies evaluate the biodegradability, or develop plastics degrading in laboratory conditions, which do not materialize in the direct environment that the plastic is expected to encounter. Even if it then degrades in its natural environment as well, the rate of degradation is usually very different from what is determined in the laboratory (Haider *et al.*, 2019). Thus, a perfectly biodegradable plastic is no better than a synthetic commodity plastic, so long as it is not provided the degradation environment in which it degrades post usage.

Biodegradability of plastics has been exhaustively studied in literature and methods for enhancing the degradation of fundamentally non-biodegradable plastics by addition of materials, such as in oxo-degradation have also been developed. Despite this the data published cannot be used for comparing two biodegradable plastics, unless they have been evaluated together in a single study in the same test conditions. Even in a case where two biodegradable plastic are evaluated and compared together, the results are specific to the test conditions and cannot be generalized to other environments (Andrady, 2007). Biodegradable plastics are also difficult to recycle. Upon mixing with the recyclable waste, they tend to act as contaminants and are difficult to isolate from the recycling stream (Kubowicz and Booth, 2017). These and several other factors raise the question of which out of recycling and biodegradation is the eco-friendlier alternative. These and other sustainability concerns associated with biodegradable plastics have been discussed as follows.

Ecotoxicity concerns in biodegradable plastics

Although the definition of biodegradation entails reduction of plastic to CO_2 , H_2O and any free form of carbon, in most plastics with enhanced biodegradability, other by-products are also released. Ecologically, it is fundamentally necessary that any such released chemical is not harmful to the ambient biome. A study conducted on brackets made of polyoxymethylene (POM), which a useful engineering polymer concluded that the primary degradation products released include Formaldehyde (Kusy and Whitley, 2005). Phytotoxicity tests on the rate of germination of radish seeds and Cytotoxicity tests on human epithelial cells using by-products usually released in hydrolysis of polyester revealed toxicity. It was also observed that aromatic compounds are more harmful than the aliphatic by-products (Kim *et al.*, 2001). Even polyurethane sheets have been demonstrated to release MDA (4,4-diamino diphenyl methane), into an activated vermiculite environment (Degli-Innocenti *et al.*, 2001). While certain plastics such as aliphatic-aromatic polyester Ecoflex® have been tested to degrade completely leaving behind no toxic residue (Witt *et al.*, 2001), there is huge number of commercial partially or fully biodegradable plastics which have not been evaluated with respect to the nature of degradation by-products.

Where the rapid biodegradation of any plastic material would solve the problem of plastic waste accumulation, release of toxins during degradation introduces the question of whether in case of mass utilization and disposal of such a plastic, the release of the same toxin in bulk into the environment will create a bigger problem than waste generation. Ecotoxicological concerns therefore form a viable part of the big picture which needs to be analyzed before a plastic walks the markets as a potential biodegradable plastic.

Oxo-biodegradability

Oxo-biodegradability is the accelerated environmental degradation induced by incorporation of certain additives to the non-biodegradable polymer matrix. This especially inspired interest in enhanced degradation of petroleum-based plastics such as Polyethylene (PE) and other polyolefins (Chiellini *et al.*, 2006; Vogt and Kleppe, 2009). The additives involved in this method, known as prodegradants are metallic salts of carboxylic acids and dithiocarbamates, utilizing transition metals such as Cobalt, Manganese, Copper, Iron, Nickel, Vanadium and others. These salts catalyse the breakdown of molecular chains, especially when the polymer is subjected to heat, which results in embrittlement and subsequent fragmentation of the plastic. Usually, along with prodegradants, antioxidants are also added in the plastic to avoid initiation of degradation while the plastic is serving its life.

Scott (1995) discussed the involvement of peroxide groups and free radicals in the cleavage of polymer chains in the presence of heat and oxygen, which the initiative step in biodegradation (biodeterioration). Presence of transition metals triggers a redox reaction with peroxides which yield rapid formation of free radicals. The molecular bonds are further severed by these free radicals. It has however been realized over years that rapid fragmentation through oxo-biodegradation produces micron size particles called microplastics, beyond which prodegradants can cause no further fragmentation. These microplastics are still resistant to complete biodegradation and persist in the environment for long intervals of time (Kubowicz and Booth, 2017). Microplastics have several detrimental impacts on the environment, especially concerning accumulation in marine ecosystem, wherein they collect hydrophobic pollutants and upon ingestion by fauna, pose the potential threat of transferring additives and pollutants to the marine food cycle (Cole *et al.*, 2011). Despite misleading advertisements portraying oxo-biodegradable plastics in the light of fully biodegradable plastics, this is conspicuously not true. However there still exist multitudinous debates and deliberations on whether the concept in general can be utilized for the greater good in plastic waste management.

Recycling versus biodegradation: Which is greener?

Plastic waste management has not been dealt with the responsibility and awareness that it deserves as a potential environmental concern. In 2010, the gross plastic waste generated in the United States alone amounted to 31.04 million tons, which is roughly 12.4% of the total waste generated (U.S. Environmental Protection Agency, 2011). In 2015, the generated plastic waste increased to 34.5 million tons (U.S. Environmental Protection Agency, 2018). Over years, these figures have become further worse, which is concerning given that most of this plastic ends up either in landfills or in water bodies as marine debris. In proportion to the severity of this, several plastic recycling technologies have evolved and have been discussed in literature (Burillo *et al.*, 2002; Pickering, 2006; Garcia and Robertson, 2017; Ragaert *et al.*, 2017). In broad practise, the recovery of a plastic is achieved through either mechanical or chemical recycling. Mechanical recycling is constituted by collection, sorting, grinding and washing of plastics, of which any sequence of steps can be used based on the material characteristics of the plastic. While mechanical recycling does not affect the molecular composition of a plastic, in chemical recycling the plastic is depolymerized into smaller molecules, which are subsequently polymerized to form the recycled plastic. Since recycling has had ample time to advance through continuous research, it is very well-developed and ready to be implemented in most cases. Naturally, efficiently performed recycling must serve as a solution to excessive plastic waste accumulation while simultaneously reducing the fossil fuel requirements for plastic manufacture. A study performed by Chen *et al.* (2011) simulated the implementation of Japanese plastic recycling and energy recovery technologies in Shenyang, China, where out of the 3 million tons MSW generated, roughly 71% waste was left in landfills in 2008. It was observed that when implemented, the recycling models reduced the Greenhouse Gas (GHG) emissions by 1.66 kgCO₂e/kg-plastic and fossil fuel consumption by 0.77 kgce/kg-plastic. Mechanical recycling was also observed to have the maximum potential for reducing environmental impacts. This study gives a perspective of the amount of environmental gain that can be achieved by implementation of advanced recycling methodologies globally. However, while recycling thus represents a promising and viable solution for the plastic waste crisis in general, the global statistics for plastic recovery and recycling are disappointing and thwart the hope of recycling saving the day. In 2012, only 9% of the plastic waste was recycled in the United States, leaving 32 million tons of plastic waste in the national waste stream. The same year, in Europe, 38% of post-consumer plastic was estimated to have ended up in landfills. The figures are worse for the other parts of the world (Gourmelon, 2015).

There are many reasons behind the poor implementation of recycling. For recycling individual petroleum plastics, they need to be separated from the general plastic garbage. Thus, plastic waste requires sorting and separation before recycling is initiated, which is very labor intensive and requires a significant input of resources. Most plastic waste which comes from the food and packaging industry is contaminated post disposal and requires cleaning before it is recycled (Kuruppalil, 2011). Even if the resources required for establishment of recycling facilities for different commodity plastics are neglected, the continuous resource input required for sorting, separating and pre-cleaning the plastic waste is high and this could make recycling unworkable for weaker economies. Although this problem can be solved by labeling the plastic composition on the product and expecting assortment of plastics during disposal, it is highly unreasonable to expect 100% responsibility from consumers.

Fig. 6 Case 1 – Hypothetical biodegradable plastic.

Against this backdrop, biodegradable plastics have surfaced as another solution for the plastic waste crisis. While it might seem like biodegradable plastics offer an easy use and throw routine, it has been discussed earlier that most biodegradable plastics disintegrate only in very specific environments. It must thus be observed that a plastic that degrades well in an industrial composting facility, when thrown in a landfill in the natural environment is just as good as a non-biodegradable plastic that adds to the litter. In fact, a study performed in Los Angeles observed that providing young individuals with biodegradable plastics for usage increased the general littering behavior, since in accordance with the general misconception associated with biodegradable plastics, consumers generally feel discharged from the responsibility of disposing waste off properly (United Nations Environment Program, 2016). Thus, biodegradable plastics have an environmental gain to offer only when they are disposed in predefined ways, such that they reach their respective degradation environments. Notably, 100% responsibility from the consumer is required in disposing off biodegradable plastics as well, in which case it cannot be established that it is a better end of life scenario for a plastic when compared with recycling. Moreover, since the known biodegradable plastics are few, in order to meet the performance requirements of a broad range of products, usually blending or copolymerization is required. However, blending of biodegradable and non-biodegradable plastics is not recommended since upon exposure to the necessary conditions, the biodegradable component in the blend disintegrates, leaving behind small particles of the non-biodegradable component (Tokiwa *et al.*, 2009; Iwata, 2015). These small plastic fragments are difficult to manage and subsequently scatter in the environment causing plastic pollution. Copolymerization with a non-biodegradable plastic on the other hand may or may not yield a biodegradable product at the end (Álvarez-Chávez *et al.*, 2012). Therefore, there is a lack of flexibility in easy modification of biodegradable plastics for obtaining tailor-made properties for specific applications.

There are multitudinous other environmental concerns associated with biodegradable plastics. It was determined by Detzel *et al.* (2012) that unlike decaying of organic matter, biodegradation of plastics does not benefit the quality or structure of soil. In addition to this, upon degradation in landfills, biodegradable plastics release considerable quantities of methane and carbon dioxide and thus contribute to global warming. If it is hypothetically assumed that all commodity plastics are replaced with biodegradable plastics, the logical estimation of greenhouse gas emissions will be petrifying. It is thus required to simultaneously capture the evolving methane and CO_2 , which can be further used for biogas production. However, it must be realized that establishing facilities for capturing greenhouse gases from a large quantity of decaying plastic, such as industrial composting units will require investment of resources, akin to recycling.

Conclusively, which out of a recyclable and a biodegradable plastic will have minimum environmental impact is subject to a comprehensive analysis of several factors involved. It is thus required to mathematically compare between these for identifying the eco-friendlier alternative with respect to the application being considered. There are several nuances associated with plastic waste management, since it depends on factors such as public awareness and responsibility towards it, government initiative and the extent to which corporate firms are willing to invest into recycling or expensive biodegradable plastics. These factors cannot be taken into account in any statistical analysis to compare between recycling and biodegradation. Thus, to obtain a perspective of why such an analysis is needed in the first place, a hypothetical ideal scenario has been discussed.

Consider two hypothetical plastics: a biodegradable plastic which is not recycled after its service life (Fig. 6), and a non-biodegradable highly recyclable plastic (Fig. 7), both developed for a particular product which serves an average life of T-year. Such an example is chosen because cases of products made out of biodegradable plastics, recycled multiple times in their life-span are rare. If the parameters are evaluated with respect to a unit product, to serve for 5T-year, the biodegradable product must be manufacture 5 times. If the amount of resources required for manufacturing one product is R_1 and the amount of waste generated per product is X, this will require $5R_1$ resources (Energy, water, land etc.) and generate 5X degradable waste. In the case of the non-biodegradable, highly recyclable plastic, it can be manufactured once and reused for 4 times before being disposed of. This will require $R_2 + 4R_3$ amount of resources and generate X amount of non-biodegradable waste.

In between the two cases, which is a greener alternative is cannot be predicted without considering the specific application and the regional parameters. However, which out of X amount of non-biodegradable waste and 5X amount of biodegradable waste is favorable in reference to the application and the ecosystem it directly affects can be decided. Likewise, which out of $5R_1$ and

Fig. 7 Case 2 – Hypothetical non-biodegradable, highly recyclable plastic.

$(R_2 + 4R_3)$ is more, and by how much, must determine which out of recycling and biodegradation consumes more fossil fuels, and how much consumption is affordable from an environmental perspective. It is known that biodegradable plastics are in general more expensive when compared with conventional commodity plastics (United Nations Environment Program, 2016), therefore an analysis must be done to evaluate the cost involved in the two cases, as well as the technical and social feasibility of each. Thus, these and such questions must be asked and relevant analyzes must be performed to evaluate the greener alternative between recyclable and biodegradable plastics.

An example of such an analysis is the life cycle assessment performed by De Andrade *et al.* (2016) which compares the environmental impact produced by three end of life scenarios for PLA: mechanical recycling, chemical recycling and biodegradation. The reference flow for this study was 1 kg of residual PLA and three impact categories were considered, namely climate change, human toxicity and fossil depletion. It was observed that composting exhibited maximum potential for detrimental impact in all the three categories, which was significantly higher than both mechanical and chemical recycling. The impact of composting was unusually high because in the case of composting, the plastic must be manufactured again by means of the energy intensive traditional processing for every time the plastic was recycled from residual PLA. Mechanical recycling exhibits the lowest environmental impacts in all the three categories, however an associated disadvantage with mechanical recycling is that the resulting product has inferior polymer properties (Piemonte *et al.*, 2013; Żenkiewicz *et al.*, 2009). This loss of properties is not observed in chemical recycling, since repolymerization is involved, however it exhibits higher environmental impacts, since energy is invested in the chemical reactions involved.

Sustainability Assessment of Biobased Plastics

Biobased plastics are developed from monomers found in renewable resources. These materials not only serve to limit the requirement of fossil fuels for development of plastics, but also exploit the atmospheric carbon and solar energy for manufacturing the monomers through natural processes. Momani (2009) maintains that if all the existing plastics would be replaced with biobased plastics, while assuming that the energy consumed in cultivation and manufacturing of plastic products is derived from renewable resources, it would save approximately 3.49 million barrels of fossil fuel per day – which is approximately 4% of the global fossil fuel usage. Some biobased plastics such as biobased PET allow for utilization of agricultural and forestry wastes, which are otherwise mostly burnt. However, against the backdrop of depleting fossil reserves, whilst the idea of biobased plastics thus presents an attractive solution, academics have been questioning the potential of biobased plastics as more sustainable alternatives. In his contribution on green plastics, Mülhaupt (2013) asserted that the actual carbon cycle followed by biobased plastics is in fact very different from the closed carbon cycle (Fig. 8) that ideal green plastics are assumed to mimic.

There are several aspects to consider before a biobased plastic can be deemed fit to replace a conventional synthetic plastic. It is not clear whether the biobased plastics developed so far are capable of emitting less carbon than their fossil-based alternatives, since the overall carbon footprint is determined by processing as well. Moreover, since the very concept of sustainability potential rests on environmental, economic as well as social impact of a material, it is necessary for any plastic, whether or not derived from

Fig. 8 The closed carbon cycle (left), The actual carbon cycle followed by bioplastics (right). Adopted from Mülhaupt, R., 2013. Green polymer chemistry and bio-based plastics: dreams and reality. *Macromolecular Chemistry and Physics* 214 (2), 159–174.

renewable resources to be favorable with respect to all the three criteria. For example, a biobased plastic that exhibits poor thermomechanical performance, or one that is too expensive will fail to find its designated place in the industry.

Renewable Plastic $\neq$ Sustainable Plastic

General Concerns Related to Biobased Plastics

Environmental concerns

In general, the evolution of society has left behind adverse effects on several aspects of the environment. The process of sustainable development is thus complicated, since where initiatives such as biobased plastics aim to ameliorate a particular environmental problem (in this case, rapid depletion of fossil reserves), there is a possibility that these might serve to exacerbate a few other environmental problems. If the complete picture of the contemporary scenario of global development and the concomitant deleterious environmental impacts is considered, one reaches the conclusion that it is necessary to solve all these environmental problems: solving any one, and making another worse might not be a wise choice in reference to the many-sided damage that has been done to the environment. The International Life Cycle Data system (ILCD) implemented in LCA studies identifies 12 impact categories at the mid-point level (European Commission-Joint Research Center, 2010), a detailed classification for which has been provided in Fig. 9. It must be noted that fossil fuel depletion presents just one of the many potential damaging impacts of a product or process, that require immediate attention. A hypothetical biobased plastic which allows for maximum conservation of fossil reserves, but unfavorably affects any four out of the 12 impact categories might not be a very desirable material.

Another important aspect to consider is the market layout of biobased plastics, which has although exhibited rapid growth in the past decade, yet most biobased plastics are produced in very small quantities when compared with commercial fossil-based plastics. According to a report published in 2017 (Degnan, 2015), biobased plastics constitute merely 1% of the global plastic production and require only 0.02% of the available arable land for the cultivation necessary to support the entire production. This leads one to think about the amount of arable land that will be required, should the biobased plastics supplant the entire global production of plastics. Land is a limited resource as well, albeit not as limited as fossil-fuels. Mass production of biobased plastics to match the global production quantity of synthetic plastics will require an excess of arable land as well as exhaustive farming on available land. Since land is also required for cultivation of food produce, it might lead to several major crises which have been discussed as follows:

- Changes in utilization of land reflect on the economy as well as on the global environment (Turner *et al.*, 2007). The present state of global widespread hunger and rising food demands have created pressure on the existing land resources, such that the available cultivable land itself is expanding, and the need for efficient utilization of available land to meet the food demand is felt (Fischer *et al.*, 2012). Approximately 11% of the total land available is utilized for production of crops to meet the food requirements, which is slightly more than one third the portion of land that can be potentially used for cultivation (Bruinsma, 2017). It is however estimated that to feed an expected population of 9 billion people by 2050, the land used for food production must be increased by nearly 70% (Fischer *et al.*, 2012). It has further been established that climate change is expected to adversely affect food security across the world (Schmidhuber and Tubiello, 2007). Thus, the state of food crisis, along with the excessive global competition for cultivable land leaves very little room for allocating a major section of land for cultivation of feedstock for production of biobased plastics. Mass production and commercialization of biobased plastics will inevitably lead to competition with food production, in which case the latter will obviously earn preference.

Fig. 9 The classification of impact categories in accordance with ILCD. Redrawn from ILCD European Commission-Joint Research Center, 2010. Institute for Environment and Sustainability: International Life Cycle Data System (ILCD) Handbook – Framework and Requirements for Life Cycle Impact Assessment Models and Indicators. first ed. Ispra. European Commission, Joint Research Center, Institute for Environment and Sustainability. Available at: <https://eplca.jrc.ec.europa.eu/uploads/ILCD-Handbook-LCIA-Framework-Requirements-ONLINE-March-2010-ISBN-fin-v1.0-EN.pdf>.

- If the competition with food production must be dodged, it will require generation of arable land other than that being used, or is expected to be used in the future for cultivation of food. Requirement of more arable land will result in deforestation and grassland conversion for farming. It is well known that agriculture is one of the major causes of deforestation (Grau *et al.*, 2005; Benhin, 2006; Pimentel *et al.*, 1986), which in turn is followed by a host of problems such as rapid increase in atmospheric greenhouse gases, soil erosion, flooding, desertification etc. and constitutes one of the most major contributors to global climate change. Likewise, conversion of any natural ecosystem to an agricultural ecosystem is known to leave a detrimental impact on the existing water resources as well (Scanlon *et al.*, 2007). Considering these aspects, it appears that generation of excess land to support a completely biobased plastic driven industry might cost much more than its primary purpose to conserve fossil reserves.
- While the scarcity of land puts pressure on the available land for generation of more biobased plastic per unit land available, a prominent issue with enhancing the productivity of cultivable land is that it comes at a cost. This cost is either defrayed in terms of excessive use of fertilizer, pesticides and fungicides, Genetically Modified Organisms (GMOs), growth hormones and antibiotics, each of which has its individual detrimental impact on the quality of soil and the natural microbial ecosystem of the soil (Jaisankar *et al.*, 2018; Savci, 2012; Kumar *et al.*, 2005), or in the form of the extra expenditure invested in organic farming. While utilizing organic resources to enhance soil productivity is a viable solution to the problem of soil deterioration through the inorganic chemical usually used by farmers, the quantity of organic resources available is very limited and this reflects in the cost of the produce as well, due to which the organic bioplastic might exceed the financial capacity of most people. In both the cases, the feedstock grown for bioplastics suffers a major setback, which might affect its sustainability potential.
- In the discussion of plastics which must be grown in farms, it is necessary to understand the perspective of the farmer as well. Since biobased plastics are expensive, for commercial benefit, the farmer could prefer cultivation of plastics over cultivation of food. This will lead to scarcity of food, especially in countries where the entire population is barely fed. In order to maximize the profit, the farmer might be lured into practising unhealthy agricultural methods such as crop monoculture. Such practises deplete the natural quality of soil, which in the long run is not only detrimental for the environment, but also in general for the farmer. Mass production of plastics will thus require strict legislation, which optimizes the farmer's profit, prevents competition of plastics and food, generates sufficient raw material to sustain the biobased plastic industry and sufficient revenue to sustain the bioeconomy. By visualizing a bioeconomy that involves mass production of all the biobased plastics, it can be understood that it will be very delicate. In fact, such a bioeconomy which holistically replaces all commodity plastics with bioplastics

would be resting on the edge of a knife, and it will require enormous efforts and resources to keep it generally stable. Any bias towards either the environmental, social or economic scenario would not only cripple its stability, but would also leave behind impacts which will be hard to recover from.

- It is expected that mass production of biobased plastics will exhaustively employ Genetically modified microorganisms (GMO), Genetically modified crops and transgenic plants in cultivation (U.S. Environmental Protection Agency, 2011). *Álvarez-Chávez et al. (2012)* states that for improving the properties of starch and for maximizing production, the GMOs used in the cultivation of PLA and starch are an 'unknown health hazard'. This is because the effect of hybridization and genetic modification of plants and organisms on the environment and other species is not known. There is a possibility of human health hazards such as toxicity of the new gene developed, alteration of metabolic pathways and allergic reactions. While these have undisputed agricultural benefits, these have multitudinous possible environmental impacts (*Hails, 2000; Snow et al., 2005*), because of which these genetically modified organisms and crops are heavily debated on and generally discouraged.

While this discussion concludes in establishing that the available land resource is a crucial factor in analyzing the socio-economic feasibility and overall environmental impact of any plant feedstock-based plastic, which includes most of the known biobased plastics, due to challenges in the contemporary sustainability measurement methods (as discussed earlier), this aspect remains beyond comprehensive analysis. Although it is mentioned as an impact category, it is usually not included in the analysis in Life Cycle Assessment studies (*Finkbeiner et al., 2014*). In fact, there is no agreement on a standard method to assess the impact of a biobased plastic on land use, and any method that is validated may be applied (*Spierling et al., 2018*). For this reason, the many sustainability concerns that surround it, such as destruction of biodiversity, depletion of water resource, deforestation and consequent increase in greenhouse gas emissions, loss of ecosystems and climate change are also not thoroughly evaluated. Thus, it is difficult to assess even the overall environmental impact a biobased plastic is expected to have when it is mass produced.

Although there are concepts such as sustainable agriculture (*Altieri, 2018*), however mass production of biobased plastics will require aggressive cultivation to meet the global plastic needs. To what extent this can be managed with the available state of the art technology without inflicting significant damage upon the environment in terms of depletion of land resource is the question that we need to ask, based on which the scientific community must bend its course to develop alternative solutions and prospective technologies to solve the problem from either ends. In nutshell, the battle to save fossil reserves must not lead to another battle for either saving another limited resource, or recovering any other significant environmental damage.

It further becomes obvious from this perspective that most concerns associated with biobased plastics remain beyond observation because they are not mass produced like synthetic plastics. The issues discussed above and many such conditions, which might present a potential threat to the ecosystem can be analyzed only by hypothetically simulating the mass production as well as commercialization of a certain biobased plastic. This condition is in all aspects equivalent to an iceberg structure, an analogy in reference to which has been presented in *Fig. 10*. It is therefore necessary to consider a biobased plastic in this light, before the economy invests resources into it.

Fig. 10 Iceberg analogy – A comparison between the current and the prospective mass production scenarios of biobased plastics.

A study conducted on 7 fossil based plastics, 4 biobased plastics along with 1 plastic based on both fossil fuels and biomass by [Tabone et al. \(2010\)](#) delineated the alignment of the green design principles such as the “12 principals of green chemistry” and the “12 principles of green engineering” with the environmental impacts of the 12 aforementioned plastics found using Life Cycle Assessment. It was observed that when broadly correlated, adherence to green design principles yielded reduction in environmental impacts. However, when the environmental impacts of the individual plastics are observed in the same study, it can be distinguished that both the grades of Polylactic acid used, namely PLA-G (obtained by a general process) and PLA-NW (obtained from Nature-Works LLC) exhibited significantly negative impact on eutrophication and ozone depletion. Likewise, the general grade Polyhydroxyalkanoate obtained from corn grain (PHA-G) exhibited significantly negative impact on acidification and ozone depletion. It was also shown to not have a very significant contribution in conservation of fossil reserves. Simultaneously, the PVC grade obtained from fossil fuel feedstock exhibited superior potential for conservation of fossil resources than the biobased plastic PHA-G. While this study provides examples of bioplastics that consume less fossil fuels, yet contribute significant damage to the environment in other impact categories, it also verifies that it is not necessary for a biobased plastic to save the amount of fossil fuels it is intended to save. This must happen because the total consumption of fossil fuels in the entire life cycle of a plastic takes into consideration both the amount of fossil fuels invested in obtaining the raw material for plastic as well as that utilized in processing, since the energy used for commercial processing is chiefly derived from fossil-based feedstock. It must however be observed that although this study gives a perspective of the sustainability concerns associated with biobased plastics, yet it constitutes only a portion of the complete picture. This is because it neither includes the impact on land resources, and the environmental problems that follow it, nor does it consider a hypothetical mass production and commercialization scenario in which the concerned biobased plastics are as bulk-produced as the concerned fossil-based plastics.

Economic concerns

Biobased plastics constitute a relatively recent development when compared with the conventional synthetic plastics. Thus, the cost of research and development associated with biobased plastics, as well as the additional cost of production ([Thakur et al., 2018](#)) makes them more expensive than fossil-based plastics per unit weight ([Van den Oever et al., 2017](#)). Furthermore, the currently low price of oil makes conventional plastics cheaper, and the corresponding biobased plastics appear more expensive. Studies have also shown that consumers are unwilling to pay an extra amount for an eco-friendlier option and tend to incline towards synthetic plastics because of the difference in price. This however is not the case with companies ([Degnan, 2015](#)). Over the past decade, more companies have adopted a sustainability-oriented approach and switched to biobased plastics, due to which their market-price has undergone a slow decline. Also, the market price of petroleum is expected to rise in the future due to an impending deficit, the high price of biobased plastics might balance the increasing price of petroleum-based plastics. However, due to rapid progress in the development of non-conventional oil recovery processes from shale gas, it is expected that there might be an intermittent stage where fossil fuels will be available at much cheaper prices before the aforesaid rise in price commences ([Iwata, 2015](#)).

That we might witness a situation where the fossil-based and biobased plastics are equally expensive and consumers might thus shift their preference towards the more ecological alternative is a possibility in the distant future. The present situation calls for an assessment of each individual biobased plastic in reference to its life cycle, such that the factors responsible for the excessive cost can be identified and attempts can be made to develop alternative processes or technology that could provide a solution. Unfortunately, Life Cycle Costing studies have been conducted only on biofuels. Bioplastics have not been subjected to such analyzes, and thus the economic aspect of biobased plastics, which is a significant factor in determining whether the plastic will find a place in the market as well as in establishing its sustainability potential needs comprehensive study in the future. It is also necessary to distinguish between the Life Cycle Costing analysis done on biobased plastics on the basis of region, since it will depend on the local prices of petroleum and its products, which change drastically between countries.

Most governments have initiated subsidies to promote biofuels over the conventional non-renewable fuels. However, in the case of biobased plastics, such support from the government is received only in the Research and Development sector ([Philp, 2015](#)). Although the immediate solution could be governments providing similar support for expanding the usage of biobased plastics despite the high price, the relevance of this approach in the long run must be questioned. After a certain span of time, once the subsidies are withdrawn, the bioplastic market might collapse. Thus, providing subsidies serves as merely a temporary solution ([Carus et al., 2011](#)). In the long run, it is required to develop biobased plastics that settle smoothly into the economy, which can be achieved only by an in-depth analysis of where the contemporary biobased plastics are going wrong.

Individual Analysis of Common Biobased Plastics

Polylactic Acid (PLA)

PLA is a biobased and biodegradable plastic, which has been widely implemented in the packaging industry. It also finds application in textile industry, paper-coating and disposable service-ware ([Yates and Barlow, 2013](#)). The basic raw material for PLA is starch, which can be obtained from corn, sugarcane, sugar-beet, rice, sweet potato, wheat, cassava etc ([Vink et al., 2003](#)). Enzymatic hydrolysis of starch yields dextrose, which is subsequently fermented to obtain Lactic acid. Lactic acid then undergoes

either direct condensation polymerization or ring opening polymerization to produce PLA (Vink *et al.*, 2003). The mechanical properties of PLA are better than Polystyrene and comparable to Polyethylene Terephthalate, which makes it an ideal industrial replacement for both (Yates and Barlow, 2013). Due to its numerous existing and prospective applications and material characteristics, PLA is a promising bioplastic and consequently several life cycle studies have focused on evaluating the environmental impacts that PLA is expected to have in its life cycle. Three primary case studies and their results have been discussed as follows:

- (1) In a cradle to gate life cycle assessment performed by Groot and Borén (2010), the environmental impacts of sugarcane based PDLA (Poly-D-lactic acid, developed from D-lactide) and PLLA (Poly-L-lactic acid, developed from L-lactide) were evaluated and compared with standard petroleum-based commodity plastics, polypropylene, polystyrene and PET, LDPE and HDPE. The functional unit for this study was 1 tonne of plastic at the factory gate in Thailand. It was observed that in comparison with all the fossil-based plastics, non-renewable energy consumption, GHG emissions and material resource usage was less for PLA. However, PLA exhibited higher potential for acidification, eutrophication, farmland usage and photochemical ozone creation.
- (2) A life cycle study performed by Vink *et al.* (2003) investigated the sustainability of the corn based PLA, manufactured and marketed by NatureWorks®. Two grades of PLA were considered for evaluation, PLA1, the general grade and PLA B/WP, an environmentally superior grade which utilized wind power, energy saved from crop residues from corn and other and process optimization. The two bioplastics were compared with Nylon 66, Nylon 6, Polycarbonate (PC), High Impact Polystyrene (HIPS), cellophane, General Purpose Polystyrene (GPPS), LDPE, PET (Solid State Polymerization – bottle grade), PET (Amorphous – fiber and film grade) and polypropylene. Both the bioplastics exhibit less gross fossil resource consumption when compared with the other synthetic plastics. However, between the two grades, the gross fossil energy use in the processing decreased from 54.1 MJ/kg in PLA1 to 7.4 MJ/kg in PLA B/WP, which evidences the superiority of PLA B/WP. Interestingly, while all the fossil-based plastics exhibit detrimental impact in terms GHG emissions, the PLA B/WP grade has a positive impact on GHG emissions, since it utilizes renewable power during the entire cradle to gate life. In terms of water use, PLA 1 and PLA B/WP perform equivalent to the plastics that exhibit the lowest impact.

It was however observed by Yates and Barlow (2013) that the two aforementioned studies draw comparisons between PLA and other synthetic plastics on the basis of weight, which is not appropriate because different material properties needed for specific applications might require different mass of the plastics, since the material characteristics of plastics vary significantly. It is thus required that LCA studies consider the specific application and its performance requirements to draw an unbiased comparison. The study discussed henceforth evaluates and compares the bioplastics taking the reference of a unit product:

- (3) A cradle to consumer gate LCA study performed by Suwanmanee *et al.* (2013) compared polystyrene, corn based PLA and cassava starch based PLA/starch blends. The functional unit is 10,000 units of thermoform boxes and the impact categories considered include global warming potential, photochemical ozone formation and acidification potential. This study revealed that the polystyrene thermoform boxes, in the overall assessment of environmental impacts performed better than both PLA and PLA/starch blends. Amongst the several cases considered, each encompassing different manufacturing methodologies used for plastic production in Thailand and a few other assumptions, a hypothetical case in which Land Use Change (LUC) was not included in the evaluation and both the bioplastics were manufactured by Thai Integrated Gasification Combined Cycle (TIGCC) is especially interesting. In this case both the bioplastics exhibited the lowest environmental impacts amongst all the considered cases, however even in this case the overall normalized impact of PLA and PLA/starch blends was 1.59 and 1.09 times that of polystyrene respectively. Although the performance of PLA was poor in this study, it must be realized that this study does not include the end of life scenario. Since PLA and starch are both biodegradable, the effect of greenhouse gases released at the end of life, which results in an approximate carbon neutrality has not been included here.

Nevertheless, since the first cradle to gate study compared between PS and PLA and arrived at totally different conclusions, this study provides a perspective of the how the sustainability issues associated with bioplastics surface in a product unit based comparison. It also demonstrates how a slight difference in assumptions might lead to biased results.

Biobased Polyethylene (Bio PE)

Biobased polyethylene or Bio-PE is a biobased non-biodegradable plastic manufactured by polymerization of the ethylene obtained by intramolecular dehydration of bioethanol. Bioethanol used for bio-PE production is usually derived from either sugar-beet or starch, which can be obtained from wood, wheat, maize, corn etc. In contrast to this, ethylene obtained from steam cracking of naphtha, heavy oil, ethane and propane is used for manufacturing fossil-based PE. Interestingly, the level of contaminants present in both the aforementioned biobased and fossil-based ethylene grades is same (Kikuchi *et al.*, 2013). Thus, the resulting material properties and characteristics of bio-PE and fossil-PE are equivalent, which is not usually observed in biobased counterparts of synthetic plastics. It also implies that only the equipment used for manufacturing ethylene requires substitution, should a firm invest in replacing fossil-based PE with biobased PE.

A life cycle study performed by Kikuchi *et al.* (2013) compared the GHG emissions resulting from bio-HDPE and fossil-based HDPE. Since the molding of product, use and waste collection are identical for PE and bio-PE, these stages of the life cycle have not been included in the system studied in this LCA. Incineration has been chosen as the end of life scenario and its effect has been

included in the evaluation of GHG emissions since this study assumes carbon neutrality in the biobased plastic. The effect of CO₂ thus evolved in the incineration of bio-PE is negated. The functional unit for this study is 1 kg of HDPE in Japan. It was observed that all the considered scenarios bio-PE exhibited fairly less potential for GHG emissions when compared with synthetic PE. This is due to the utilization of bagasse and energy generated during production of bioethanol, the negative effect of which is considered on the GHG potential of bio-PE. Moreover, cracking of naphtha is extremely energy intensive and contributes more than twice the amount of GHG emissions than dehydration of bioethanol.

Another study performed by [Bos et al. \(2012\)](#) evaluated and compared the Non-Renewable Energy Use (NERU) potential of LDPE, bio-LDPE and PLA. The functional unit for the LCA was 1 metric tonne of product. This study evaluates grades of bio-PE developed from wheat, maize, sugar-beet, sugarcane as well as miscanthus. It was observed that all the grades of bio-PE exhibited significantly lower non-renewable energy requirement than synthetic PE in accordance with today's agricultural practises. It must however be noted that wheat and sugar-beet require maximum and minimum arable land respectively, which must affect their individual potential for other impact categories. Since the amount of arable land is limited resource and it varies between the plastics evaluated, this study introduces the idea of NERU avoided per unit hectare of land, which in this study is maximum for sugarcane-based PE. This idea is of relevance to future studies, since it optimizes the results obtained in two different but very prominent impact categories to identify the most suitable bioplastic, and such approaches can be actively used in LCA in situations where more than one impact category is sensitive. Although these results favor bio-PE, this study reveals that the NERU avoided per unit hectare of land in PLA is significantly higher than bio-PE because cultivation for a fixed quantity of plastic requires nearly 3 times as much land in each grade of bio-PE than PLA, which implies that land resource consumption might arise as an issue in mass production of bio-PE.

LCA studies are further required to evaluate the potential of bio-PE for other environmental impact categories. However, given that bio-PE does not lack in properties and produces lower environmental impacts than synthetic PE, it still emerges a promising bioplastic. Since PE is one of the most exhaustively used plastics, supplanting it with bio-PE will conserve a large amount fossil resource, however since bio-PE is itself non-biodegradable, it will hardly be a solution for the plastic waste generation. Therefore, options such PLA, which are biobased and biodegradable must also be simultaneously considered.

Product Based Case-Studies

Sandwich Composite Panel

A comparative cradle to gate Life Cycle Assessment study was conducted by [La Rosa et al. \(2014\)](#) to evaluate the environmental impacts of a sandwiched composite structure based on a partially biobased epoxy relative to that based on a fossil-based epoxy. Super Sap 100 (Resin) and Super Sap 1000 (Hardener), a material system with approximately 50% biobased content was reinforced with hemp fiber to develop the outer-skin, which was sandwiched with a panel made of granulated cork to develop the eco-sandwich panels. The traditional sandwich panel was developed from a Polyurethane based epoxy, Prime 20LV which was reinforced with glass fiber to develop the outer skin, with a core panel made out of Polyurethane foam. The chosen functional unit for this study was a block of the eco-sandwich panel of specified dimensions, however for the purpose of a fair comparison between two structures intended for the same application, the thermal insulation property of both the panels was made equal by varying the thickness of the insulating material used in the traditional sandwich panel (PU foam).

Based on the production inventory of granulated cork panels, the heat for required for boiling the raw cork as well binding of cork was obtained from burning of cork dust, in order to minimize the electricity used in the process, since electricity is obtained from fossil-energy. The water used in the process was obtained from a well and it was recycled several times to further minimize the environmental impact. Abiotic depletion was thus minimized for this study, however the same cannot be assumed for all industrial processes. A comparison was subsequently drawn between the two plastics, the two fibers used for reinforcement as well as the overall structure, however for the purpose of this discussion, only the comparison between the plastics is considered and analyzed.

In comparison with the petroleum-based epoxy, the biobased epoxy exhibited significantly reduced potential for abiotic depletion and moderately reduced potential for acidification, global warming, cumulative energy demand, ozone layer depletion, and freshwater aquatic ecotoxicity. However, the biobased plastic simultaneously exhibited a moderately increased potential for eutrophication and human toxicity along with an eight-fold increase in the terrestrial ecotoxicity potential. Although terrestrial ecotoxicity has a critical effect on ecosystems, the study concludes that the biomass-based plastic used in this analysis has an overall reduced carbon footprint and does not compete with food sources. It must however be observed that the relative importance of the different impact categories changes with geographical and local ecological parameters. For example, in a region where the terrestrial ecosystem is damaged or sustains a very delicate balance, the increased terrestrial ecotoxicity might present a very significant threat, and thus the relevance of this biobased plastic could be negated in this particular region. Apart from this, the ozone depletion potential for the partially biobased plastic Super 100/1000 is calculated to be zero, which is a very surprising result considering the fact that the petroleum-based plastic used in the study (LV20 Epoxy) exhibits negative impact on ozone depletion and that there is approximately 50% petroleum-based content in this partially biobased plastic as well.

The most limiting aspect of this study is that due lack of availability of primary data for both Super Sap 100/1000 and LV20 Epoxy system in LCA databases, comparison was made by assuming a standard petroleum-based epoxy in place of the used

epoxies in both the developed sandwich composite panels. In this reference, the results obtained in this study might change drastically if the original data for both the epoxy systems is used in place of the assumed standard commercial epoxy. However, this study still provides a perspective of the sustainability potential that can be achieved in biobased plastics and that a complete mathematical evaluation might unearth hidden detrimental impacts on the environment which the bioplastics can have. Considering that this study was conducted in 2014, another concern that surfaces is that the contemporary LCA databases are deficient in the data necessary for a much-needed critical analysis of all bioplastics. A possible reason for this is that many local LCA studies which are conducted to evaluate the region-specific impacts of bioplastics cannot be generalized. Thus, the produced data uncertainty, a major drawback of the LCA method reduces the legitimacy of many studies conducted under similar assumptions. It is therefore necessary to take relevant steps for enriching and updating the existing databases.

Water Bottles

The global statistics for plastic consumption in the form of water bottles are alarming. In 2007, United States alone produced two million plastic bottles every 5 min (Palliser, 2010). Since most plastic bottles around the world are made from Polyethylene Terephthalate (PET), which is a fossil-based plastic, this quantity of production implies significant consumption of oil. In 2006, to meet the demand for plastic bottles in the packaged drinks industry, approximately 17 million barrels of oil were used (Palliser, 2010). It is reasonable to assume that since PET is highly recyclable, most of the waste generated from plastic bottles must be recycled to reduce the amount of fossil fuel needed in making fresh batches of bottles, however in reality only 20%–30% of plastic bottles are recycled (Palliser, 2010). It has thus been very necessary to find biobased alternatives to solve this problem. So far, biobased PET and PLA have surfaced as suitable alternatives, and the industry is willing to adopt them on a large scale. In fact, the Coca-Cola company, which is one of the largest manufacturers of bottled beverages introduced 30% biobased Dasani water bottles in 2009. This company has been further planning to replace the fossil based plastic bottles with 100% biobased PET bottles (Chen *et al.*, 2016). On the other hand, due to lower fossil fuel consumption in its manufacturing as well as its biodegradability, PLA is being studied as a prospective biobased plastic for bottle production (Papong *et al.*, 2014; Gironi and Piemonte, 2011). In this section, three conducted Life Cycle Assessment studies have been discussed which evaluate the sustainability issues that might be associated with these two alternative biobased plastics in reference to water bottle production.

Fossil-based PET versus 100% biobased PET

This comparative cradle to gate LCA study performed by Chen *et al.* (2016) focuses on evaluating the sustainability potential of a biobased PET bottle relative to that of a fossil-based PET bottle. It is interesting that the processing of both the fossil-based and biobased grades of PET differs only in the origin of raw materials. Polyethylene Terephthalate is manufactured by polymerizing a mixture of 30% Ethylene Glycol and 70% purified Terephthalic Acid (PTA). In the case of fossil-based PET, Ethylene Glycol is obtained by hydration and oxidation of ethylene, which is extracted from natural gas and Paraxylene extracted from Xylene mixture in petroleum is oxidized to obtain PTA. On the other hand, for manufacturing biobased PET, the ethylene obtained from bioethanol is hydrated and oxidized to obtain Ethylene Glycol and Isobutanol extracted from biomass is subjected to pre-treatment, enzymatic hydrolysis and fermentation to obtain Paraxylene, which is further oxidized to obtain PTA. The processing steps following the production of Ethylene Glycol and PTA include polymerization into amorphous grade PET granulate, which are then processed into bottle grade granulate by solid state polycondensation. These bottle grade granulate are then converted to bottles via injection blow molding. These steps are the same for both fossil-based PET and biobased PET, and consequently the nature of both plastics is the same. The usage and the end of life scenario is thus the same for either and does not need evaluation in the Life Cycle study.

The functional unit for this study is 1kg of PET bottle. Corn, switchgrass, wheat straw and fossil feedstock were used to manufacture 4 different grades of Ethylene Glycol, while forest residue, corn stover and fossil feedstock were used as raw material for 3 grades of PTA. Thus, 12 grades of PET, from a combination of each grade of EG and PTA were produced and analyzed. Out of all the developed grades of PET, the grades which utilized PTA generated from forest residue exhibited overall lowest environmental impact when compared with those that utilized PTA developed from corn stover and fossil resources. Considering the results obtained for all the 12 grades together, it was concluded that extraction of biomass feedstock and pre-processing to obtain Isobutanol in the case of fully and partially biobased grades produced much more emissions than processing of fossil-based feedstock. This is because a significantly large amount of energy is spent in agricultural operations and subsequent manufacturing of immediate chemical products. The global warming potential of the forest residue-based PET grades was 27% and 21% lower than that of corn stover and fossil-based PET grades. The group of PET grades that utilized corn stover PTA had the maximum potential for acidification, whereas the fossil-based PET grades had minimum acidification potential.

In this study, it has been assumed that the biobased feedstock has been obtained by collecting the forest residue, which is otherwise not fit for trading and is burnt. This process is known as slash pile burning and is a major contributor of emissions due to incomplete combustion of biomass. The negative impact of slash pile burning, which was avoided by exploiting the concerned biomass in production of biobased PET grades has been subtracted from the overall environmental impact observed in the PET grades. It is observed that if the effect of avoiding slash pile burning and other similar impacts were ignored, the biobased PET grades would perform poorly in the LCA study. Moreover, uncertainty in the impacts due to

Isobutanol production and slash pile burning have rendered a significant influence on the final environmental impact obtained at the end of the study.

Since a large range of PET grades from fully biobased to fully fossil-based were analyzed in this study, mixed results were obtained in general. However, in several aspects, the fossil-based grades were observed to have lower environmental impacts than the biobased grades. It is certain that biobased grades save a certain amount of fossil fuel due to their origin, however the subsequent processing and its impacts largely govern the overall environmental impact. Thus, this study clearly demonstrates that just being biobased does not qualify a plastic as the more sustainable option.

Fossil-based PET versus PLA

This comparative cradle to grave LCA study performed by [Papong et al. \(2014\)](#) considers and evaluates the potential of PLA as suitable alternative for water bottles relative to the fossil-based PET. Lactides can be conveniently mass produced by fermentation of biomass-based substances containing carbohydrates such as starch. Thus, for an application like plastic bottles, which requires production in bulk quantity to meet the global needs, PLA might be able to provide for the mass production. It is also well known in literature that PLA consumes lower fossil energy as compared to Polypropylene, Polystyrene, and fossil-based PET ([Madival et al., 2009](#); [Vink et al., 2007](#); [Uihlein et al., 2008](#)). For these reasons, a PLA grade developed from Cassava starch was chosen for this comparative analysis. The functional unit for this study is 1000 units of 250 ml bottles.

The global warming potential as well as the total consumption of fossil energy for PLA was found to be less than PET. In fact, when compared with PLA derived from corn, the cassava starch-based PLA exhibited lower fossil consumption, since despite use of inorganic fertilizers and pesticides, the yield of corn is usually less. However, PLA evidences significantly approximately 5 times the impact in eutrophication and moderately higher impact in acidification than fossil-based PET. This study also evaluates the performance of PLA while assuming that energy conservation methods such combined heating and power generation systems are adopted for an eco-friendlier processing of PLA. Despite this, the calculated eutrophication potential for PLA is more than twice that of PET, which clearly indicates that eutrophication might be a serious implication of PLA processing. It must therefore be observed, that in PLA processing, additional measures be opted to counterbalance the eutrophication effect that a PLA plant is expected to produce.

As discussed earlier, PET is manufactured by polymerizing Ethylene Glycol and purified Phthalic Acid. This process is extremely emission intensive, and consequently PET exhibits more than 8 times the potential for human toxicity than PLA. For the end of life case, four scenarios are considered and analyzed for the produced environmental impacts: Landfill, incineration, recycling and composting. It is concluded that for PLA, incineration is the eco-friendliest alternative, followed by recycling and composting. As far as recycling is concerned, PLA is blended with other polymers for most of its applications, which makes recycling expensive and technically complicated, in comparison to which PET is very easy to recycle. Although in conclusion this study favors PLA, this conclusion is based mostly on the Greenhouse Gas emissions observed in both cases. In reality many more fundamental aspects need consideration such as which impact category requires the most attention for particular applications, as suggested by [Gironi and Piemonte \(2011\)](#) in another comparative LCA between the same systems i.e., PLA and fossil-based PET.

This study calculates the environmental impacts of PLA derived from corn in comparison with PET. The cradle to gate analysis establishes that while PLA conserves fossil resources, it causes substantial damage to the ecosystem quality and human health. Considering the weightage assigned to macro-impact categories by the LCA Suisse group (40% ecosystem quality, 40% human health and 20% resources), both PLA and PET perform equally. In the cradle to grave analysis, PLA fares better than PET when recycling is assumed to be the end of life scenario, however apart from the above-mentioned nuances associated with the recycling of PLA, it also depends on plastic waste sorting systems, which are not very well developed and practiced, which makes recycling of PLA further difficult.

Diapers

Diapers have been subject to meticulous evaluation since these not only directly affect the sanitation and health of children, but are also a potential consumer of fossil resources and a source of significant waste generation, owing to the rise in global population which leads to increase in the demand for diaper. LCA studies conducted on reusable cloth diapers have revealed that raw material production and manufacturing require attention with respect to the environmental aspects. For disposable diapers however, the same studies assign maximum importance to the end of life scenario ([Aumonier and Collins, 2005](#)). Although composting appears to be the most suitable method for getting rid of used wet diapers, presence of non-biodegradable plastics and components in disposable diapers prevents complete biodegradation. Several eco-friendlier alternatives to the conventional disposable diaper have been developed and numerous analyzes have been performed to understand the sustainability potential of the various types of diapers available today. One such study established that 'glue-less' diapers are both 7%–170% eco-friendlier and 11% cheaper than the conventional product ([Mendoza et al., 2019](#)). It is however necessary to take into consideration that since diaper has a critical effect on child health, it is not possible to convince a majority of consumers to switch to an option that is widely socially accepted and trusted. Any new development thus also requires a study to evaluate and establish the effect and compatibility of the used plastics with the skin as well as an in-depth S-LCA study to determine whether it is social acceptance can displace the conventional diaper.

A cradle to gate LCA study performed by [Mirabella et al. \(2013\)](#) considers disposable diapers manufactured and marketed by WIP S.p.A., in which the plastics used in a conventional diaper are replaced with biobased and biodegradable plastics. The

disposable diaper consists of three layers made of Polypropylene (PP), Polyethylene (PE), Superabsorbent Polymer (SAP) along with an Acquisition and Distribution Layer (ADL). The eco-friendly diaper analyzed in this study includes replacement of Polypropylene with Polylactic acid (PLA), SAP with fluff made of organic Totally Chlorine Free (TCF) pulp certified by PEFC (Program for the Endorsement of Forest Certification), Polyethylene with Mater-Bi® and the ADL is made out of 50% PP and 50% PLA. The functional unit for this LCA is one diaper. Since the data for composting supply chain is not available on databases, the end of life scenarios for the WIP S.p.A diapers could not be analyzed.

The environmental effect in reference to 18 impact categories is investigated. It is observed that out of the four layers of the diaper as well as the transportation and packaging processes, the TCF pulp contributes the maximum detrimental impact in 7 out of 18 categories. Amongst the 7 impact categories it contributes more than 60% impact in agricultural and urban land occupation, natural land transformation, water depletion. Although the replacement of SAP with TCF pulp leaves behind a very small quantity of SAP in the eco-friendly diaper, it is still the second most major contributor to the environmental impacts overall, which implies that SAP replacement is indeed environmentally a very smart choice. While PLA shows extremely promising results in the potential for ozone depletion, human toxicity, ionizing radiation, marine ecotoxicity, fresh water eutrophication and agricultural land consumption, it exhibits detrimental impact on fossil resource consumption, terrestrial ecotoxicity and particulate matter formation. It is to be noted that a biobased plastic, PLA contributes approximately 30% of the total fossil resource consumption amongst all the components, including transportation and packaging. Amongst all the bioplastics employed in the diaper, the contribution of Mater Bi is not more than 15% in any impact category, and thus it presents a very promising bioplastic for this application.

When a comparison was drawn with the LCA results of the conventional disposable diaper, the eco-friendly diaper surprisingly performed better only in 7 out of the 18 impact categories. It was also observed that the bioplastic-based diaper has more severe environmental impact in categories related to land resource consumption and transformation, eutrophication and water depletion. Upon normalizing the results of all the impact categories, both the diapers overall exhibited significant potential for human toxicity, marine ecotoxicity, freshwater eutrophication and natural land transformation. However, when the normalized results of the eco-friendly diaper were compared with the conventional diaper, the former performed better in 3 out of the 4 aforementioned categories. It is therefore concluded that since the eco-friendly diaper fares better than the conventional diaper in most of the categories in which any kind of diaper is expected to yield maximum detrimental impact, it solves its purpose of reducing environmental impact and must be preferred.

Notably, if the land resource consumption was not studied along with the other impact categories, the effect of the diaper on water depletion could have been less since a large quantity of water resource is invested in irrigation. Considering the performance of the bioplastic-based diaper in all the categories together, there is a possibility that the results for this eco-friendly diaper would have been very promising if the land resource consumption was not evaluated, since its performance declines significantly only in this and its related categories. In this light, the other LCA studies which do not include evaluation of the land resource category and conclude in the favor of the bioplastic appear incomplete and biased. It is evidenced in this study that land resource consumption has a drastic impact on the overall sustainability potential, and it is possible that upon evaluation, this impact category would alter the results of other LCA studies as well.

Future Outlook

A future that enjoys harmony between the environment and the human population can only be realized by means of sustainable development, the goal of which is to strike a balance between environmental, social and economic impacts of a process. This balance is delicate because compromising with any of these three pillars might not seem like a significant damage but will eventually add up to the situation where sustainable development will not be feasible anymore. In this light the most ideal material system for sustainable development should be one that optimizes environmental impacts, economic feasibility and social acceptance. The question of whether the contemporary bioplastics in any way come close to such a material system still needs to be answered. Due to the shortcomings of LCA studies performed on bioplastics and lack of S-LCA and LCC studies, it is impossible to see the complete picture. What can be concluded from LCA studies are fragments of the overall evaluation that cannot be extrapolated to concrete conclusions. However, an analysis of the performed sustainability measurements establishes that the bioplastics do have detrimental environmental impacts, which remain beyond sight unless they are explicitly evaluated.

Even if the solution is sought in bioplastics and the forthcoming century must witness supplanting synthetic commodity plastics, the realized and unrealized environmental, social and economic impacts associated with unit products will cumulatively produce enormous impacts during mass production. Several sustainability issues associated with biobased plastics which can be identified only by visualizing a hypothetical mass production scenario such as competition with food production, mass depletion of land and water resources and cost uncertainty have been evaluated in the previous discussions. Therefore, the discussed hypothetical simulation of mass production for each individual bioplastic which is aimed at any industrial application will provide a foresight of such impedances to sustainable development and hence is indispensable. However, since the available sustainability measurement methods provide no such tools, it is necessary at this stage to develop mathematic methodologies focusing on this. The end of life scenario has an equally significant contribution in environmental and economic impacts. An analysis for identifying the ideal end of life scenario out of recycling, biodegradation and incineration, an example of which has been discussed, is required.

Fig. 11 Design of a sustainable bioplastic.

It is therefore very necessary at this stage that the discrepancies associated with sustainability measurement are eliminated and the sustainability potential of bioplastics is holistically evaluated. Although, the discussed bioplastics in this contribution exhibited detrimental environmental impacts and several social and economic concerns were associated with their mass production, it does not imply that these cannot develop into ideal material systems. For the purpose of designing a bioplastic, the general guideline to be followed is given by the 12 principles of green engineering. However, these are generalized concepts which give little insight into the protocol or strategy for developing of a sustainable bioplastic. This leaves bioplastic material design a process with no definite ends.

What can be done?

- The purpose for designing a bioplastic must initiate from the requirement of replacing a specific synthetic plastic used in a particular product. Since environmental, social and economic conditions vary regionally, the general goal of the design must be to develop a sustainable bioplastic that satisfies the balance needed for sustainable development in reference to regional production and commercialization of the bioplastic. For this, the availability and abundance of local land and water resources must be identified, such that cultivation of the crop which yield the raw material for the bioplastic can be initiated without restricting the production of food and other crops. The choice of raw material must minimize the environmental impacts such as soil depletion, which its production is expected to produce. For example, a plastic crop which can be cultivated in crop-polyculture with food crops, where each crop symbiotically replenishes the nutrients the other crop depletes can be a good place to start. The cultivation of plastic crop must be analyzed for other such possible environmental impacts.
- Once the raw material is identified, the regional environmental and economic conditions must be analyzed to assign weightage to the different environmental impacts possible. Subsequently a processing route must be designed such that it yields minimum to no environmental impacts in categories which cannot be damaged any further. It is essential that the cost of the developed product is such that it can be commercialized easily. Processes such as pre-consumer recycling, biodegradation and incineration must be implemented to aid the sustainability potential of the product being designed.
- The end of life scenarios possible must be evaluated, while taking into consideration the environmental and social impacts of these, the regional awareness and responsibility of consumers towards waste management as well as the available government incentives for implementing the concerned waste management option. For example, biodegradation may not be a suitable solution for a region, from where the waste usually finds its way into the marine environment, unless an industrial composting facility is established and the it is ensured that the plastic waste reaches it upon disposal.
- Thereafter, the developed bioplastics must be filtered for the options which offer the required properties. The bioplastics which do not pass this filter can then be considered for other applications, for which their properties are suitable.
- Once the product life cycle has been designed, all the filtered bioplastics must undergo comprehensive LCA, LCC and S-LCA studies, which holistically evaluate all the impact categories and yield an unbiased wholesome picture. This step will identify the environmental and other impacts which were left unrealized in the design of the life cycle. These impacts must then be addressed by modifying the design of the processing route, or the choice of raw materials etc.

- For the remaining bioplastics, each of which has the relevant set of material properties and is environmentally, socially and economically suitable for regional commercialization, a hypothetical mass production must be simulated to identify the hidden sustainability issues which surface only in mass production. The bioplastic which passes this filter is the ideal sustainable material system for implementation in the desired application and subsequent commercial use (Fig. 11).

Several such protocols can be developed based on the requirements and factors, which are specific to either the region, the application or the plastics. However, it is essential that the protocol holistically evaluates the bioplastic and the implemented bioplastic is stable environmentally, commercially and socially.

Summary

In this article, the evaluated and possible sustainability issues associated with biobased and biodegradable plastics have been discussed. The drawbacks associated with LCA which prevent an unqualified assessment of bioplastics have been highlighted. Since bioplastics constitute both biobased and biodegradable plastics, both of these and the sustainability issues associated with them have been analyzed. Biodegradability and recycling have been compared for identification of the eco-friendlier end of life scenario and the need for simulating hypothetical mass production to foresee the sustainability concerns associated with bioplastics has been emphasized. Assessment of individual bioplastics and three product-based case studies have been discussed to provide an insight into the sustainability issues of existing bioplastics.

Introduction

Commonly used traditional polymeric materials such as high or low density polyethylene (HDPE or LDPE), polypropylene (PP), poly(ethylene terephthalate) (PET), polystyrene (PS) or poly(vinyl chloride) (PVC) have good resistance to water, gases, temperature and chemicals. They also have high mechanical strength, transparency, low mass and low price, as well as, ease dyeing. Moreover there is a lack of interaction between them and the product with which they stay in contact with. These materials have a negative impact on the environment, therefore the use of polymers with a minimal carbon footprint should become widespread. Due to environmental issues, more attention is being paid to renewable resource-based plastics. Furthermore, degradable or biodegradable polymers attract a lot of consideration in view of the current interest not only in sustainable development but also in recycling, environmental protection, and healthcare. From the sustainability perspective, (bio)degradable polymers are considered to be safe for the environment and to represent an interesting and fairly versatile alternative to conventional polymers. There is also increasing demand for (bio)degradable polymers that have been designed as materials for multi-faceted applications with a specific lifetime. Currently, there are challenges related to the design of materials that are stable in use, and at the same time susceptible to microbial attack during organic recycling.

According to the polymers origin or origin of the raw material needed to obtain them, (bio)degradable polymers can be classified as follows: natural polymers (biopolymers), polymers from renewable resources (of biological origin), and those from non-renewable/fossil resources such as oil, natural gas and coal (synthetic polymers) (Table 1).

Polymers from renewable resources differ from natural polymers by the fact that the synthesis is purposely initiated and caused either by microorganisms or by chemical means. The biopolymer is specifically “a polymer formed by living organisms; man-made polymer is not a biopolymer”. According to the terminology of the International Union of Pure and Applied Chemistry (IUPAC), a degradable polymer is “a polymer in which macromolecules are able to undergo chain scissions, resulting in a decrease of molar mass.” Biodegradation is “caused by enzymatic process resulting from the action of cells”, but *in vivo* degradation resulting “only from hydrolysis by the water present in tissues and organs” must be defined as hydrolytic degradation. An *in vitro* abiotic degradation by isolated enzymes is “a degradation caused by the catalytic action of enzymes” and is not considered as biodegradation. The fact that a polymer is from renewable raw materials is “composed or derived in whole or in part of biological products issued from the biomass” does not mean that the material is biodegradable. Biodegradation is an enzymatically catalyzed hydrolysis of the ester, amide, or urethane polymer bonds in the process of surface erosion; because enzymes do not penetrate deep into the polymer matrix, this leads to water-soluble oligomers metabolized by microbial cells. In the cases of high-molar-mass polymers, the first degradation step is conventional hydrolysis, which is not catalyzed by enzymes, and the depolymerization intermediates are finally metabolized by microorganisms (Rydz *et al.*, 2015a,b, 2018).

Environmentally-Friendly Polymers

Natural Polymers

Due to their natural origin, all naturally occurring polymers are biodegradable, since, for any polymerase activity that leads to a natural polymer, there is depolymerase that can catalyze the degradation of this natural polymer to maintain the balance of nature. The advantageous properties of natural polymers are their bioactivity, antimicrobial and antioxidant properties, renewable origin, relatively low cost, high prevalence, and the fact that they have no negative impact on the environment.

The essential polysaccharides used in material applications are cellulose and starch. These polymers are classified by their monosaccharide components and their ring size (furanose or pyranose), their absolute configuration (*D*- or *L*-), the sequences and linkages between them, the anomeric configuration of linkages, as well as any other substituents present in the molecule. Starch is a hydrocolloid that contains two types of polymers: amylose (20%–30%) and amylopectin (70%–80%) with *D*-glucopyranoside repeating units. This polymer is found in corn, potato, wheat, rice, barley, oat, and soy in the form of granules of different shapes and sizes from 0.5 to 175 μm . Starch, depending on the source, has different proportions of amylose and amylopectin. It has very favorable physical properties, such as high barrier properties (low gas and water permeability), transparency, ability to give the desired color and good rheological properties. Cellulose a polysaccharide and one of the most commonly occurring natural polymers is found in all plant materials, some amoebae, sea animals, bacteria, and fungi. Cellulose consists of very long macromolecular chains of one repeating unit: cellobiose. This polymer's molecules have hydrophilic nature, poor solubility characteristics, and highly crystalline structure. Moreover, cellulose is infusible and insoluble in all organic solvents. Chitosan is other linear polysaccharide consisting of β -(1 $\rightarrow$ 4)-linked 2-amino-2-deoxy-*D*-glucose (*D*-glucosamine) and 2-acetamido-2-deoxy-*D*-glucose (*N*-acetyl-*D*-glucosamine) units.

Table 1 Classification of (bio)degradable polymers

Polymer group	(Bio)degradable representatives
Natural polymers (biopolymers)	● Polysaccharides: cellulose, starch, chitin and chitosan, alginate, hyaluronic acid; ● Poly(amino acid)s: poly(γ-glutamic acid), poly(ϵ-L-lysine), cyanophycin; ● Peptides, proteins: whey protein, soy protein, zein, casein, wheat gluten, gelatin.
Polymers from renewable resources (artificial biopolymers)	● Polymers with microbiological origin (biotechnological polymers): polyhydroxyalkanoates (PHA)s, microbial cellulose; ● Polymers from renewable monomers (from bioderived monomers): polylactide or poly(lactic acid) (PLA), polyglycolide or poly(glycolic acid) (PGA), poly(butylene succinate) (PBS)^a, poly(butylene adipate-co-terephthalate) (PBAT)^a.
Polymers from non-renewable resources (non-natural/man-made polymers)	● Aliphatic polyesters: poly(ϵ-caprolactone) (PCL), poly(3-hydroxybutyrate) (PHB), poly(butylene succinate); ● Aliphatic-aromatic copolyesters: poly(butylene adipate-co-terephthalate); ● Poly(amino acid)s; ● Polycarbonates; ● Polyanhydrides.

^aBiobased currently in development.

Chitosan is obtained by partial alkaline *N*-deacetylation of chitin. Chitin is a component of shells of crabs, shrimp, crawfish, and insects. Depending on the preparation method, the degree of deacetylation (the ratio *D*-glucosamine to *N*-acetyl-*D*-glucosamine) may range from 30% to 100%. The composition of the polymer affects the crystallinity, surface energy, and degradation rate of chitosan. Due to the fact that chitosan has a rigid and compact crystalline structure and strong intra- and intermolecular hydrogen bonding it is insoluble in water and alkaline media. This polymer has antimicrobial activity and can, therefore, be used to extend the shelf life of food and as a component of biodegradable edible films for food. Hyaluronic acid is a high-molar-mass, linear polysaccharide classified as glycosaminoglycan, consisting of the repeating disaccharide units. Hyaluronic acid is present in all organisms. The highest concentration of this polymer is found in soft connective tissue. The traditional method of obtaining hyaluronic acid was extraction from rooster combs and bovine vitreous humour. This polymer offers many unique advantages as a building block for biomaterials. Hyaluronic acid is used commercially as an aid in ophthalmic surgery.

Poly(amino acid)s consist of amino acids linked through amide bonds. These polymers are characterized by biocompatibility, bioabsorbability, and adequate mechanical properties. Some of the most important α -amino acids containing polymers are poly (aspartic acid), poly(L-lysine) and poly(L-glutamic acid). Proteins are thermoplastic heteropolymers built from different polar and non-polar α -amino acids. Amino acids can form intermolecular linkages that result in different interactions. This offers a wide possibility of chemical functionalities and functional properties. Fibrous proteins, such as silk, wool and collagen are neither soluble nor fusible and must be used in their natural form for those reasons. Collagen is the elementary protein component of animal connective tissues. Collagen contains various polypeptides built from mostly glycine, hydroxyproline, proline and lysine. The flexibility of the polymer depends on the glycine content. More flexibility is obtained by an increase of the content of glycine. Due to their unique biological properties collagen is used in biomedical applications. Zein is a protein mixture varying in molecular size and solubility, classified as a prolamin. This mixture contains 44%–79% of the endosperm protein depending on the variety of corn and separation method. Zein has both hydrophobic and hydrophilic properties and due to its poor mechanical properties it is mainly used as a protective, impermeable coating, due to its good gas barrier, biodegradation and biocompatibility properties. Soy protein is another widely known protein that is isolated from soybean and are processed into high protein commercial products such as soy flour and soy concentrates by dehulling and defatting processes, are processed into high protein commercial products such as soy flour and soy concentrates (Ulery *et al.*, 2011; Kunduru *et al.*, 2016).

Polymers From Renewable Resources

Considering renewable resources for the production of polymeric materials, two different directions can be adopted. The first is the direct conversion of renewable resources into the final polymer. In the second, the monomer or other substrates are obtained from renewable resources and next are transformed directly or via few, chemical stages into final polymer. Polyesters with microbiological origins, such as polyhydroxyalkanoates illustrate the first direction. Polylactide, an aliphatic (bio)degradable and a biocompatible thermoplastic polyester, is an example of the second direction of the production of polymeric materials from renewable resources.

Polyhydroxyalkanoates are a family of natural biodegradable polyesters produced by genetically modified plants or microorganisms, as their reserve material (Fig. 1).

The assimilated coal is biochemically processed into the monomer (the appropriate hydroxyalkanoate), which polymerizes in the presence of PHA synthase (PhaC) enzyme. Obtained PHA are storage inside the cell in the form of sub-micron inclusion bodies. Under normal conditions the amount of polymer in the bacteria cell is in the range from 1% to 30% of their dry mass, but when the fermentation conditions are controlled some bacteria can accumulate PHA up to 90%.

Fig. 1 General molecular formula of PHAs, where R is H for poly(3-hydroxypropionate) (PHP), CH₃ for poly(3-hydroxybutyrate) (PHB), C₂H₅ for poly(3-hydroxyvalerate) (PHV), C₃H₇ for poly(3-hydroxyhexanoate) (PHHx), C₅H₁₁ for poly(3-hydroxyoctanoate) (PHO), C₇H₁₅ for poly(3-hydroxydecanoate) (PHD).

Fig. 2 Methods to obtain PLA.

The microorganisms are the main source of PHA, because of their ease of obtaining from the cell by the solvent extraction method. Under *in vivo* conditions the polymer is in an amorphous state, but after extraction it takes a crystalline form. Molar mass of polymer depends on microorganism type and the fermentation conditions. PHAs show non-toxicity and biocompatibility while retaining the properties of classic plastics. They are characterized by good barrier properties. The water vapor permeability of PHA materials is lower compared to other (bio)degradable materials (e.g., PLA). Poly[(*R*)-3-hydroxybutyrate] (nPHB) is the best-known polyester from PHA group, it is a brittle, crystalline (up to 80%) and thermoplastic linear homopolymer. Unfortunately, this polymer is susceptible to the thermal degradation in the range of its melting temperature (T_m) because T_m is close to the decomposition temperature, which hinders its processing and thus limits its applications. nPHB is obtained by enzymatic polymerization of (*R*)-3-hydroxybutyric acid with coenzyme A. Control of fermentation conditions and the type of carbon source leads to obtaining different copolymers, such as poly(3-hydroxybutyrate-*co*-4-hydroxybutyrate) (P3HB4HB) or poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV), which are an alternative to non-biodegradable plastics. The introduction of (*R*)-3-hydroxyvaleric acid into the polymer chain during the microbial fermentation results in a PHBV copolymer with a lower degree of crystallinity. PHBV can be processed by traditional methods at a temperature lower than the polymer decomposition temperature. The PHA properties can be modeled by controlling the fermentation conditions and providing a suitable carbon source. Mechanical properties of PHA depends on the type of substituent group present and a variety of polymers, from rigid to brittle may be obtained. Blending of different PHAs increase their application range, hence the reason why PHA copolymers seems to be an interesting alternative in the production of biodegradable materials (Rydz *et al.*, 2015a,b).

Poly(lactide) is the most popular synthetic (bio)degradable polymer obtained from renewable raw materials. PLA is biocompatible thermoplastic, with possibility to process it in a large-scale commercial processing equipment by conventional methods and can replace classic thermoplastics. PLA has a high modulus and tensile strength, it also is resistance to UV radiation and fats, has good barrier properties of flavor and odor, good printability and processability, however, is brittle and degrades easily as temperature rises. PLA is obtained in two ways: direct polycondensation of lactic acid (Fig. 2(A)) or ring-opening polymerization (ROP) of lactic acid cyclic dimer, known as lactide (Fig. 2(B)). The lactic acid used is obtained from the fermentation of raw materials derived from renewable resources such as starch, cellulose or simple sugars (glucose, dextrose, maltose, sucrose).

ROP leads to high-molar-mass polymer with good mechanical properties. In the direct condensation, materials of low to intermediate molar mass are obtained because a solvent is used and a higher reaction time is required. The properties of PLA depend from the molar mass and stereochemical composition of the repeat units and their distribution along the polyester chain. Homochiral PLA (poly(*L*-lactide) (PLLA) or poly(*D*-lactide) (PDLA)) is isotactic stereoregular polymer with glass transition temperature (T_g) in the range of 55°C to 65°C. PLLA and PDLA are the semicrystalline polymers while the poly(*D,L*-lactide) (PDLLA) is more amorphous. Therefore, the products made of PLA have a very wide range of mechanical properties from soft, flexible plastics to rigid durable products. However, it is not suitable for some applications, so the physical properties of this material can be

improved either by blending with other polymers or with copolymerization. The biocompatibility and non-toxicity of PLA and its degradation products made this polymer a very interesting material for medical applications. The important role in its practical application plays the PLA crystallinity. Devices made of semicrystalline PLA are characterized with good mechanical strength and found application e.g., in packaging industry. The blends (physical mixtures of at least two structurally different polymers) of PLA with poly(ethylene oxide), poly(ethylene glycol), PCL, poly(vinyl acetate), nPHB, cellulose acetate, PBS and poly(hexamethylene succinate) as well as the plasticizers such as oligolactide, glycerol, low-molar-mass triacetin and citrates are also used (Nowak and Pająk, 2010).

Polymers From Fossil Resources

Man-made synthetic biodegradable polymers have more advantages than natural polymers because, they can be tailored to give a wider range of properties and can be transformed into a degradable material for specific applications. Generally, they are biologically inert, have more predictable properties, and the source of raw materials used to obtain such polymers is more readily available. The most commonly used synthetic polymers from non-renewable sources are poly[(*R,S*)-3-hydroxybutyrate] [(*R,S*)-PHB], poly[(1,4-butylene adipate-*co*-1,4-butylene terephthalate)], poly(butylene succinate) and its copolymers: poly(1,4-butylene succinate-*co*-1,4-butylene adipate) (PBSA) and poly(1,4-butylene succinate-*co*-1,4-butylene terephthalate) (PBST) as well as poly(ϵ -caprolactone).

A synthetic analog of aliphatic biopolyester, nPHB – (*R,S*)-PHB – is considered as a suitable modifier for (bio)degradable polymers, such as the highly crystalline PHAs of bacterial origin or the brittle PLA. PHBs and their block and graft copolymers can be obtained by direct copolymerization of the corresponding epoxides with carbon monoxide or anionic ring-opening polymerization of (*R,S*)- β -butyrolactone in the presence of the anionic initiators activated by macrocyclic ligands, such as crown ethers or cryptands. (*R,S*)-PHB is used for the physical or chemical modification of natural polymers by blending or by block or random copolymer synthesis. The blends of (*R,S*)-PHB with natural PHBV (containing 10 mol% of 3-hydroxyvaleric units) are compatible within the range of the tested compositions: 10%–50% of the (*R,S*)-PHB content. The PHBV copolymers with lactide, ϵ -caprolactone, β -lactones and higher lactones, as well as with poly(methyl methacrylate), poly(vinyl alcohol), poly(ethylene glycol) or polysaccharides are obtained by polymerization occurring in the presence of a macroinitiator or copolymerization of macromonomer. The copolymers obtained have a different chain structure: statistical, grafted, block (from diblock to multiblock) and different architecture: linear, comb and star. Anionic polymerization of at least two monomers with similar reactivity allows obtaining polymers with a statistical distribution of these two types of constitutional units in the polymer chain.

PBAT is an aliphatic-aromatic copolyester obtained from terephthalic acid or dimethyl terephthalate, adipic acid and 1,4-butylene glycol. Preparation and biodegradation studies of aliphatic-aromatic copolyesters, especially PBAT, have enabled the implementation on an industrial scale production of a compostable plastic called Ecoflex[®] produced by BASF Germany. PBAT is a flexible material with functional properties allowing its widespread use. The PBAT copolyesters combine the good functionality of aromatic polyesters with the biodegradability of aliphatic polyesters and can also be used in the form of a blend with other polyesters. The change of PBAT properties can be obtained by blending it with e.g., maleic anhydride or PHBV. The blends of PBAT with PLA and thermoplastic starch, have properties similar to polypropylene. Poly(butylene succinate) is produced from ethylene glycol or 1,2-ethylenediol, 1,4-butanediol and succinic acid. Its mechanical properties are comparable with PP and LDPE. The properties and biodegradability of PBS depends on amounts and type of glycols or diols and diacids used during production. Addition of adipic acid gives the PBSA copolymer. Increasing in the susceptibility to microbial attacks of poly(tetramethylene succinate) (PTMS) is achieved by introducing the carbonate into its crystal structure.

PCL is a synthetic, linear aliphatic polyester produced by the ring-opening polymerization of ϵ -caprolactone. It shows good biodegradability and susceptibility to hydrolytic degradation. However, due to the low flow temperature (around 60°C) its processing is much more difficult (Rydz *et al.*, 2015b, 2018).

Global Carbon Life Cycle and Principles Concerning Sustainability

The carbon cycle is a biogeochemical cycle through which carbon is converted between the earth's different types of coal reservoirs in the biosphere, pedosphere, geosphere, hydrosphere and the atmosphere. The earth's atmosphere contains carbon primarily in the form of carbon dioxide (CO₂) and, although CO₂ levels in the atmosphere are not constant, it is the fifth most abundant gas therein.

Polymers are carbon-based materials and, in the ecosystem, carbon is part of the biological life cycle; it is therefore vital that carbon-based polymeric materials are sustainably adapted to the natural carbon cycle. The traditional petrochemical-based polymers produced by cracking feedstocks from raw materials, such as natural gas and crude oil, are known for the difficulties in managing them sustainably and ecologically, due to the lack of degradation. Therefore, the conversion rate of non-renewable resources (petroleum-based polymer materials) into CO₂ is in total imbalance with the rate at which they are consumed and renewed (Fig. 3). In this way, carbon is not managed sustainably and ecologically: it is either locked up in landfills due to lack of degradation and practical recycling procedures of plastics or released as CO₂ into the environment through the incineration of

Fig. 3 Global carbon life cycle.

plastics, rather than its transformation back into carbon resources. The latter is also outpacing nature's CO₂ recycling capability through photosynthesis, causing a significant increase in the global CO₂ level.

Significant advances have been made in the development of several ecofriendly materials with low environmental impact. These can be obtained from different types of carbon-based feedstock including agricultural products, such as corn or soybeans, and from other sources like algae or food waste. The development of environmentally friendly materials and the sustainable production of polymers from renewable feedstock is vital for our declining natural resources and therefore ecofriendly polymers are becoming increasingly important from the sustainability point of view. Biomass provides a path for renewable sources of both carbon-based energy and polymer ecomaterials. Using annually renewable crop resources or biomass as raw material for polymer production, the rate at which CO₂ is renewed equals its consumption, which is naturally sustainable. Also, the use of synthetic (bio)degradable materials does not involve long-term deficits, and their resources are renewed in a short time. Biobased polymers are characterized not only by their origin from renewable sources but also by the following: easy disposal, recycling, the reuse of waste, biodegradation or composting and the fact that they are health-safe. The impact on human health is reduced, along with a reduction in pollution and material use as well as the creation of energy efficiency.

Carbon footprint (CF) and life cycle assessments (LCA) of polymer materials are methods used to quantify the sustainability of plastics and their global carbon life cycle. Carbon footprint is a term that had a wide appeal and has been driven mainly by people outside the research community, partly because the term gives a much easier way to calculate and grasp the concept of carbon emissions. But it also takes only one factor into account and therefore oversimplifies the notion of CO₂ emission. In the life cycle assessment, however, the discussions also include many other factors such as the quantification of methane losses, condensation trails, ozone formation, and cirrus clouds, and many other technicalities. Life cycle assessment is a much more robust way of highlighting the full environmental impact of a process, product or activity from cradle to grave, or cradle to gate, depending on what stage of the investigation is the focus of interest. According to the International Organization for Standardization (ISO), there are several key steps in performing and implementing LCA. That is, the environmental impact of all phases of the product's life are assessed (inputs and outputs), from raw material extraction, manufacturing, distribution, storage, usage, recycling, reuse and disposal. LCA is a good measure of the environmental performance of the selected product and creates a holistic picture, which avoids solving one environmental issue but creating a new one in the process. Multiple substances can be assessed separately or simultaneously to better understand their contribution to various environmental problems. A well-implemented LCA contributes to important knowledge which not only enables producers to identify more sustainable methods of production, use and disposal of the polymer, but can also give an opportunity for further environmental adjustments as needed. The problem with LCA is the complexity of the process involved and the time it takes to identify and quantify all the material and energy flows related to the product, process or activity. Additionally, it is difficult to get hold of reliable data and it is also complicated to establish which flows provide the cause of any environmental impact.

The LCA databases used to quantify the environmental sustainability of biobased and/or biodegradable polymers. For example, poly[(R)-3-hydroxybutyrate] is compared to the petroleum-based polypropylene and polyethylene. Despite several controversial issues related to the nPHB production, such as the high energy demands, the LCA of this polymer shows that it is much more environmentally friendly than polyolefins. The study, however, did not consider the effects of polymer disposal and it was anticipated that the incineration of polyolefins will add a further burden while giving nPHB additional benefits. This is a very common procedure for many LCA studies, and it is due to the scarcity of the end of life data. Although a lot of factors must be considered when comparing biobased polymers with traditional petroleum-based polymers, the differences between the biobased polymers are not that significant. The energy demand for feedstocks production and lack of composting facilities, as most plastics end up in a landfill, are some of the common issues hampering the full benefit of biobased polymers. The current understanding

of biopolymer distribution in waste streams is also insufficient and is hence the reason why the resultant cradle to grave life cycle environmental impacts remain ambiguous.

Problems such as the lack of dedicated waste collection systems and recycling methods are also regarded as barriers to sustainability. High energy demands, lack of extensive end-of-life (EOL) data, and also those of high material and water requirements from the farming and production processes, give a greater environmental burden and contribute negatively to the overall LCA outcome. Just because certain plastics are produced to be environmentally friendly, does not mean that they can be dumped into a landfill and become biodegradable under unfavorable conditions. It must be created a safe and sustainable way to facilitate the speedy degradation of biobased polymers and return them back to the carbon cycle in a sustainable manner (Harding *et al.*, 2007; Hottle and Bilecand Landis, 2013; Kyulavska *et al.*, 2018).

Applications of Environmentally-Friendly Polymers

For each polymer application, understanding which materials are optimal for their purpose allows for the exact selection of the right polymer material. In recent year's research and development above new materials including (bio)degradable plastics with well-defined properties, from both service and environmental point of view, has shown continuous progress.

Medical, Pharmaceutical and the Dental Sector Applications

The fact that (bio)degradable polymers are readily absorbed by the human body drives both the scope of application and the extent to which they are used in medicine and dentistry. Some of the examples of their usage include assorted medical and dental devices or their components, surgical sutures, (bio)degradable components used in the repair of ligaments. These polymers also found a wide application in the manufacturing of tools used during a variety of surgical procedures as well as for the making of devices that are permanently implanted. The accessibility of coated or time-released drugs requires the availability of carefully chosen and formulated polymers that will allow for a uniform release of predetermined doses on medication over time. (Bio)degradable polymers, such as PGA, PLA, poly(glycolide-co-lactide) (PLGA), poly(*p*-dioxanone), poly(glycolide-co-trimethylene carbonate) and PCL are used as materials for surgical sutures or resorbable implants, stiffening dressings and controlled drug delivery systems. In dental procedures, the (bio)degradable polymers are used as void filler following tooth extraction (porous polymer particles can be packed into the cavity to promote quicker healing) and a (bio)degradable film that can be positioned to prevent epithelial migration following periodontal surgery. There is expanding need in the field of orthopedics for joint replacements, items used in the repair of fractures, bone fillers and bone cement, as well as artificial orthopedic constructs used to replace parts that sustained irreparable damage. PGA, PLA and its copolymers, PHA and PCL are particularly desirable for orthopedic devices due to their excellent biocompatibility and the possibilities to adjust physical properties and degradation properties to a specific application. Implants are being developed using biopolymers such as collagen, elastin, hyaluronic acid, chitosan, silk, and starch. The synthetic and natural polymers have been combined with nano-hydroxyapatite (nano-HAP) or tricalcium phosphate (TCP) which allows for the design of implants that have bone-like compositions. A different example of the application of these polymers is the production of composites that simulates bone tissue growth. (Bio)degradable polyesters can also be used as a coating on a medical device or as a completely (bio)degradable devices such as anastomosis rings and tissue staples, ligating clips, tissue engineering scaffolds vascular grafts and stents.

Packaging Sector and Food-Services Sector Applications

Delivery of food products to the point of sale or to the consumer requires a large and varied amount of packaging product, each designed to serve its unique purpose. The function of packaging is threefold: the material from which it is made must be approved for direct contact with food, the design of packaging must protect its contents from external contamination, and also must serve to protect it from loss of flavor. Additional requirements address transportation and storage requirements. Starch is readily available in large volumes and at relatively low cost. It has also attractive physical properties, low permeability of gases and water (barrier), transparency or ability to impart desired color (optical), which makes it one of the best candidates for biodegradable food packaging. Thermoplastic starch is used for food wrappings and cups, plates and other food containers. Because starch has poor mechanical properties and poor resistance moisture which place limits on it uses this polymer can be blended with various polymers such as PLA, PCL or PVA. The polymer/starch blend can be used in the production of flexible and rigid films, allowing for thermoforming into rigid injection molded packaging trays and for coating of paper and cardboard (direct contact with food). Another polymer used for packaging material is cellulose and its derivatives, like cellulose acetate. It is extensively used in the packaging of fresh products and baked goods. Chitosan can be blended with PCL, protein such as zein, gluten, soy protein or whey protein. PLA is a proper candidate as green food packaging material, due to its high molar mass, easy processing by thermoforming, and (bio)degradability. PLA is finding practical application in the production of beverage bottles, transparent rigid containers, bags (also from PBAT), jars, food containers, disposable cups, coating for all types of packaging and film packaging foams. Materials based on PLA and PHBV have shown effective application for the production of thermoformed containers for food packaging. PHAs such as PHB and its copolymers: PHBV, poly(hydroxybutyrate-co-hydroxyhexanoate) (PHBHx), poly

(hydroxybutyrate-*co*-hydroxyoctanoate) (PHBO), poly(hydroxybutyrate-*co*-hydroxyoctadecanoate) (PHBOd) and P3HB4HB can be used in packaging for deep drawing foods such as bottles, disposable cups, laminated foils and fast food.

Agriculture and Horticulture Applications

Recent trends in the agricultural application include the use of natural and synthetic (bio)degradable polymers such as agar, starch, pectins, alginates, chitin, lignin, cellulose and its derivatives, PLA and PCL to replace traditional plastics. Soil retention sheeting, agricultural foils, seed or fertilizer tapes and binding materials, threads, clips, staples, bags containing fertilizer, envelopes of ensilage and trays of seeds, plant pots are being replaced by (bio)degradable equivalents and disposable items so that the used (bio)degradable materials does not have to be removed after use. Natural polymers along with synthetic (bio)degradable polymers such as PLA or PCL can be used as carriers in controlled release systems of pesticides, herbicides, nutrients, fertilizers, pheromones to repel insects. The active agent can either be dissolved, dispersed or encapsulated by the polymer matrix or coating, or is a part of the macromolecular backbone or pendent side chain. PBAT can be used as greenhouse tunnels and mulching foils.

Automotive and Transportation Sectors Including Aerospace Applications

Current objectives of the automotive industry are to reduce fuel consumption and CO₂ emission. One way to accomplish this is to reduce vehicle mass. This offers an opportunity to expand biobased and (bio)degradable polymer applications suitable for the automobile construction. (Bio)degradable polyesters can be used in automotive manufactures as coatings for interiors or exteriors, thermoplastic elastomers, fiber reinforced thermosetting, shape memory and self-healing items, piezoresistive components for interior trims prototypes and for strain gauges for vibration monitoring. One of the most commonly used materials is composites. Those materials have good mechanical properties and the relative facility of combining them with other materials. In the automotive industry, biobased polymer composites, but only those that can be recycled, could be used in structural parts of the vehicle's body such as door handles, dashboard fascia, panels, floor trim, scooter frames, secondary paneling or interiors and underbonet. About 50% of all interior components, including safety subsystems, door and seat assemblies in commercial vehicles are made of plastics. Starch-based polymers are used as an additive in the manufacturing of tires. Starch reduces the resistance to the movement, the consumption of fuel, and reduces fine greenhouse gas emissions. Industrial sectors, such as construction, automotive and transportation sectors including aviation and aerospace use additive manufacturing as an integral tool in the design process. Three-dimensional (3D) printing technology allows us to build concept cars and aircraft, but it also allows for the rapid printing of components using experimental material and compares them with traditionally made parts.

Building and Construction Sector Applications

Unlike the automotive industry, the building construction is striving to reduce its CO₂ footprint and emissions. Ecofriendly buildings are intended to provide a healthier place to live and work. Such materials include laminated wood plastic components, polymer compositions (polyesters with jute fibers or fiber-reinforced polymers). Biobased and/or (bio)degradable plastics can be used as molds for truss joints, high thermal insulation rigid foams, new mortars or concretes, piezoresistive strain gauges for monitoring mechanical deformations of structures. PLA-based composites could be used as internal window profiles or, with the addition of aluminum hypophosphite, can provide flame retarding properties to some construction materials. The application of the composites determines their classification: structural (bridges, and roof components), and non-structural (windows, exterior components, composite panes, door frames).

Consumer Goods Applications

This category of goods includes a very large number of items ranging from domestic implements to recreational sports items, toys, and consumables. A new generation of adhesives, paints, engine lubricants, and construction materials, as well as golf tees and fishing hooks, is made of (bio)degradable polymer materials. Toothbrush handles and adhesive tape backing include chemically modified plant cellulose. Traditional materials used in the manufacturing of coffee capsules, which are used in large numbers, are replaced with starch-based materials, or with (bio)degradable polyesters. A (bio)degradable material used in 3D printing made from non-genetically modified maize corn starch is used to produce clothes using 3D printing method. Additionally, testing is underway to use it in the manufacture of toys. Cups, plates, bowls and shoes can also be made using this material. (Bio)degradable material from a marine shell is used to make Lego blocks, plastic balls, model toys, pens and art knives.

Electric and Electronic Sector Applications

Composites based on hollow keratin fibers and chemically modified soybean oil find applications in electronics as new low dielectric constant material. Other electronic devices that use (bio)degradable polymer-based materials include capacitors, communication devices, loudspeakers with advanced functionalities and paper-based displays made from wood lignocellulose microfibers-based polymers or batteries for microelectromechanical systems. Electroconductive plastics were developed to

manufacture electronics from sustainable sources. This is accomplished by spinning of different nanofibers individually or by hybridizing with other materials and incorporating them with suitable biobased polymers which can produce nanocomposites as possible superior structural components (lighter than their micro counterparts). These materials find application in a variety of electrical, optical and biomedical items such as components of various functional devices. Ecofriendly materials can be used in vacuum cleaners, as housing for power tools, and for portable electronic equipment including cellular phones. Electronic industry is also using (bio)degradable materials such as PLA/CORDENKA® composites. PLA can also be functionalized with various additives. PLA and kenaf are used as composites in electronic applications such as compact disks or computer cases. PLA can be enhanced by special technology to achieve properties such as conductivity, significant improvement in thermal stability or mechanical properties and are suitable for 3D printing technology, giving almost unlimited possibilities in the production of ready-to-use (bio)degradable polymer-based electronic materials (Rydz *et al.*, 2018; Włodarczyk *et al.*, 2018).

Three-dimensional Processing of (Bio)degradable Materials

The additive manufacturing (AM) is a type of manufacturing technology that produces 3D objects and this has received considerable attention in recent years. The process creates a 3D object in which materials are joined layer upon layer, while the structure is usually designed and processed under 3D computer modeling software.

There are different types of methods or 3D printers available today and they differ both in the way the successive layers are deposited as well as in the materials that can be used. Some of the most common are digital light processing (DLP), fused deposition modeling (FDM), stereolithography (SL), selective laser sintering (SLS), selective laser melting (SLM), laminated object manufacturing (LOM) and PolyJet technology. However, it seems that SLS and FDM are attracting growing interest since they produce high durability complex parts and allow for the quick identification of any design issues. The 3D technology is in rapid development and it has moved from being used as a tool to create and verify prototypes to becoming a powerful method of manufacturing final products from a myriad of different materials, such as metals, paper, liquid, wax, powder, wood and different types of polymers. Polymers are by far the most utilized material and there is a growing number of polymers currently used for 3D printing technology such as polyamides or polyesters.

Both naturally occurring and synthetic polymers are used for 3D printing filaments and each one has its own advantages and limitations. Naturally occurring polymers like collagen, chitin, gelatin, chondroitin, chitosan and various types of alginate can be used for tissue and organ engineering as well as diagnostic platforms. However, polymers such as polyamides, PCL, PLA, PGA, PLGA and different types of polymer blends offer unlimited opportunities for various medical purposes. This include both tissue engineering and drug delivery systems as they offer rather more possibility of tailoring the chemistry to the specific requirements, such as a specific end group, molar mass, polymer composition and biocompatibility. For the polymer industry, this is a manufacturing technology that has enormous potential and it is predicted that the adoption of 3D manufacturing will continue to expand in the future. Furthermore, the prospect for biomedical applications of 3D printing is the most interesting area (Rydz *et al.*, 2015a; Włodarczyk *et al.*, 2018).

Factors Affecting the Rate of (Bio)degradation Processes

There are many factors that have an influence on the (bio)degradation process of (bio)degradable materials, which are not only concerning the polymer itself but also exposure conditions. From the point of view of polymer, the molar mass, type of functional groups, crystallinity, type of additives, pretreatment of material and surface to volume ratio play an important role in its (bio) degradation. Polymers are rather resistant to the microbial attack, as long as their molar mass remains high. Hydrolysis or photodegradation can cause a decrease of molar mass until the level that microorganisms are able to utilize it. The enzymes have easier access to the polymer chain in the amorphous regions, where the less-ordered packing occurs. Higher crystallite edge surface in the polymer leads to higher degradation rate, because this rate is dependent on the availability of substrate. Increasing of the surface to volume ratio in the polymer also increases the availability of substrate and hence the degradation rate. The influences of the polymer additives on the degradation progress depend mainly on the type and the amount of it (Chandra and Rustgi, 1998; Rydz *et al.*, 2017).

If the polymer is suitable for organic recycling the rate of its (bio)degradation depends on the composting conditions. Aerobic decomposition of organic matter by the microorganisms is an important process in any ecosystem. This biological process occurs naturally anywhere where the organic matter has contact with air and humidity. The composting process mimics and intensifies the processes occurring in nature by creating optimal conditions. The rate and course of composting are influenced by the type and amount of microorganisms, temperature, pH, the presence of oxygen, humidity and carbon to nitrogen ratio (C/N). In the compost plenty of microorganisms are active. At the beginning of the composting process, the bacteria colonize the wastes. When the compost starts to dry the fungi begin to dominate. During the first composting phase the temperature rise is caused by mesophilic organism's action. When the temperature reaches at 45°C the thermophilic organisms continue the process, raising the temperature of the material to 65°C or higher. This phase is very important for the quality of the compost as the heat kills pathogens and deactivates weed seeds. Also, the high temperature phase of composting can accelerate the degradation progress of (bio)degradable polymers. When the high energy sources start to end, the cooling and maturation phase begins. Too high and too

low pH is toxic for microorganisms, it causes the change of ionization state of amino and carboxyl groups of proteins. If pH drops below 6 the microorganisms are dying and the decomposition of organic matter runs slower. pH above 9 causes the release of nitrogen to the atmosphere in the form of ammonia. Hence the nitrogen is not available for microorganisms. Optimal humidity for the composting process is in the range of 45%–60%. Exceeding of the 65% value promotes the formation of anaerobic zones, while achieving the value below 40% the nutrients become difficult to access for microorganisms. The main of (bio)degradable polymers are based on synthetic polyesters or modified biopolymers that are susceptible to enzymatic and/or hydrolytic degradation. The higher the moisture contents, the more quickly the degradation of moisture sensitive polymers occurs. However, the balance from the technological point of view must be preserved. In order to maintain optimal humidity of the compost among others the aeration of waste is used. This technique is also necessary to obtain the optimal temperature. Proper amount of oxygen causes the correct biological activity of microorganisms. The microorganisms which are responsible for composting process needs to receive the nutrients in the form available to them. The right concentration and proportions of the necessary elements must be ensured. To the most important ingredients needed for the proper functioning of microorganism belongs: carbon (C), nitrogen (N), phosphate (P) and potassium (K). Carbon is the energy source for microorganisms and nitrogen determines their speed of growth. C/N ratio of organic matter is an important factor that determines decomposition by the microbial. Composting occurs most efficiently when the C/N ratio is between 25:1 and 35:1 (Jędrzak, 2008; Rydz *et al.*, 2017).

Polyesters (Bio)degradation Studies under Laboratory and Real Conditions

Research on novel polymeric materials and their susceptibility to degradation are nowadays very important from both scientific and technological points of view. Advanced polymer materials are under consideration for new applications e.g., as superconductors, engineering materials and (bio)degradable packaging materials. (Bio)degradable materials are regarded to be essential also in medical and biological usages and therefore there are very important for human beings. Developing such polymeric materials for many applications is therefore of great importance. Products made from (bio)degradable polymers after using are susceptible to organic recycling, which reduces the environmental impact of polymer waste and allows for the rational utilization of these materials under composting conditions in accordance with new trends in the management of this type of waste. However, the efficient use requires basic research necessary to determine the relationship between the structure of such materials (including the topology of the macromolecules), properties and degradation mechanism. Prediction studies are needed in the area of advanced polymer materials particularly (bio)degradable polymers in order to increase efficiency and to define and minimize the potential failure of novel polymeric products before and after specific use. Due to the wide spectrum of potential applications of (bio)degradable polymers in medicine, in the field of compostable polymer packages (especially of long shelf life products such as cosmetics or household chemicals) as well as in agrichemical formulations degradation studies in different environments provide basic knowledge and a valuable service by increasing understanding and helping prevent future problems. Such innovative approach may help to design novel polymeric materials and to avoid the failures of existing ones. Therefore, it is so important to determine the degradation conditions during virtual testing of (bio)degradable polymer materials for the intended applications. Materials for specific applications must not only perform specific functions but also must meet acceptable standards of safety during use and exhibit chemical and physical stability. The complete replacement of conventional plastics with environmentally friendly polymers is impossible to achieve without recognizing and assessing the possible risks. In the case of (bio)degradable polymeric material, it should be chosen so as to minimize the impact of environmental conditions leading to (bio)degradation during usage. Therefore, modeling and simulation of degradation allows the prediction of the behavior of a complex polymer system during their use and disposal based on the comprehensive characterization of degradation pathways.

Thermo-, photo-, radio-, oxo- and mechanical degradations are important degradation mechanisms considering aging and the pre-programmed lifetime of particular polymeric materials. Photochemical degradation is initiated by the action of visible or ultraviolet light in the presence of chromophore groups (absorb light). These reactions can occur in the main chain and in the side groups. Mechanical degradation occurs under the influence of stress and takes place primarily in areas of material weakness (aggregates of small-molecule polymer fractions, inclusions of foreign bodies, end of chains, residual monomer, solvent, etc.). The atmospheric degradation proceeds according to mechanisms of oxidation (thermooxidation) and photooxidation (photo-degradation). During the oxidation molecules with a low molar mass are formed and groups containing oxygen are appeared along the polymer chain or on its ends. Thermooxidation takes place in the entire volume of the polymer and occurs at an increased temperature and in the presence of oxygen. Photooxidation occurs under the influence of UV radiation, mainly on the polymer surface. Photooxidation causes the breakdown of the chains into free radicals. Atmospheric degradation leads to the changes in the chemical structure of the polymer (branching, crosslinking), reduction in the molar mass (chain cracking), damage (cracking, scratches), which leads to changes in the physical properties of the materials.

The susceptibility of polymers and polymeric materials to (bio)degradation depends primarily on their chemical structure. For this reason, the origin of polymers, whether they are obtained from renewable (biomass) or non-renewable (fossil) resources, does not refer to the biodegradation. But the combination of biodegradation with the use of renewable resources for the production of bioplastics is a unique opportunity to adapt their life cycle to the natural cycle of matter. (Bio)degradable polymer evaluation studies for the final products for long-term applications involves virtual tests under different environmental conditions, including biodegradation under laboratory conditions (disintegration/biodegradability tests), pot degradation experiment, degradation under industrial composting conditions (static composting open-air pile, KNEER container system, BIODEGMA system) and

weathering test (the degradation of materials under natural atmospheric conditions). Often, under laboratory conditions, the reference degradation tests are carried out, parallel to real-world tests. During those tests, degradation products (collected during degradation) can be investigated and their structure or interactions between the polymeric material and the product with which it stays in contact can be determined. Under industrial composting conditions neither the collection process nor the compatibility test is practically a viable option. The behavior of polymeric material in nature and its factors impact (sunlight, rain, wind) on the samples tested should also be determined. The weathering tests are carried out in placing the sample on sloping shelves oriented to the sun. In the northern hemisphere, these stands are at an angle of 45° to the south, and in the south it is at a 45° angle to the north. This setting guarantees the full use of the whole spectrum of solar radiation. To achieve the maximum level of degradation, high temperature and humidity are also necessary, which can be achieved in tropical areas. Florida possesses all these features and therefore it is the global standard for natural aging methods. Generally, the biodegradation under natural conditions is more complicated process compared to degradation in controlled conditions and requires a complex and comparative procedure. Biodegradation studies under the industrial composting conditions can be referred to biological tests conducted *in vivo*, because they reflect the real conditions prevailing during organic recycling. Biodegradation carried out under laboratory composting conditions using a Micro-Oxymax respirometer, is in this case a reference to *in vitro* tests. During the biodegradation process under aerobic conditions, the material decomposes that leading to the formation of CO₂, water and solid residue – biomass. Thus, an evaluation of the progress of this process can be the measurement of released CO₂ or consumed oxygen (O₂), using the experimental technique such as of titrimetric analysis, gas chromatography or the automatically system – respirometer Micro-Oxymax. During incubation in the respirometer, the amount of released CO₂ from samples tested is monitored as a function of time. Obtained the cumulative value of CO₂ is used to determine the degree of biodegradation of studied materials. The degree of biodegradation (*B*) is calculated as the ratio of measured in the test amount of evolved CO₂ to the theoretical amount of CO₂ (*Th*_{CO₂} that can be produced by total oxidation of the tested material):

$$B = (m_{\text{CO}_2\text{test}} - m_{\text{CO}_2\text{blank}}) / Th_{\text{CO}_2} \times 100\%$$

where: *m*_{CO₂test} and *m*_{CO₂blank} are the amount of CO₂ [mg] evolved from tested material and blank inoculum, respectively.

The assessment of soil and compost quality, in which the biodegradable materials are incubated, is carried out on the basis of phytotoxicity tests in accordance with the guidelines contained in the Guide for Organization for Economic Cooperation and Development, OECD 208; EN 13432: 2000, by the method based on the comparing of the ability to grow of selected terrestrial plants in standard conditions with growth of plants on the tested soil and/or compost (pot experiment). The average values of fresh and dry matter of plants that grew on soil and/or compost after the degradation of the samples tested should be similar to those of control plants. Similarly, the growing percentage of the examined plants within each species examined should be similar to the control samples. As a result, this visual assessment of plant damage should confirm the lack of harmful effects of the samples examined on tested environments. The European Norm EN13432 that recommended composting as a method of organic recycling post-consumer, biodegradable polymeric materials waste including also test scheme and the procedure to assess the compostability. The organic recycling is recommended for waste susceptible for biodegradation and fragmentation during biological treatment, without an adverse effect on the composting process, and a negative impact on the quality of the compost obtained. In contrast to bacterial polyesters such as polyhydroxyalkanoates, which directly undergo biodegradation by many microorganisms present in the environment, the high-molar-mass PLA is colonized by relatively few microorganisms and more often takes place the water-catalyzed hydrolysis of those material. But generally, for (bio)degradable polymers the first step of biodegradation under natural and laboratory conditions is a chemical hydrolysis (mainly by random chain scission) which leads to the reduction of molar mass. In the next step, called mineralization the oligomers formed are bioassimilated by microorganisms as an energy source. The final result of biodegradation under natural conditions (composting process) is compost, where water and CO₂ are emitted into the atmosphere. The material can be qualified for organic recycling if it meets the following criteria: (i) for the process of industrial composting, lasting a maximum of 6 months, at least 90% of the material transformation into CO₂ is required, (ii) under anaerobic conditions during the 2 months of testing the degree of degradation (determined based on the separated biogas) should be 50%. If there is such a possibility, then biodegradation tests should be performed for packaging in the final form (pilot scale study). This allows specifying possible negative effects associated with the biodegradation process during the recycling of large quantities of the final products waste.

Although environmentally friendly polymers have gained much attention as possible substitutes for conventional plastics, the factors that influence their sustainability are often difficult to examine. Before the widespread use of any novel (bio)degradable/renewable polymer is advocated the full environmental impact (ecobalance) must be assessed. Moreover, the polymer material can interact with the product in which it stays in contact with such as food, cosmetics or the human body. These interactions can lead to changes in the product as well in the polymeric material structure and should be studied in detail. For this purpose, research in the field of safety engineering is carried out, checking the behavior of polymeric material/product systems in simulated and natural conditions. Obtaining basic knowledge about these interactions will allow better targeting of innovative applications of advanced polymeric materials and avoiding problems when using final products (e.g., cosmetics or food packaging and implants). End-products made of (bio)degradable polymers when subjected to the composting process will be (bio)degradable, and if they get into the environment in an uncontrolled way, they will undergo environmental and atmospheric degradation under the influence of the factors there (Musiol *et al.*, 2018).

Introduction

The increase in population worldwide and technological advances aimed new consumption habits which have led to the accelerated growth of large amounts of wastes. Currently, the amount of waste of all types generated worldwide is 1.3 billion ton/year, with a prospect for 2025 increasing to 2.2 billion tons per year ([Al-Fakih et al., 2019](#)). As a consequence, there is growing interest looking for new ways where these can be minimized or even used as a resource for added value. The recycling of by-products generated during industrial processes should be a priority action.

Wastes and by-products have great potential for its incorporation in the construction sector as raw material contributing to the called Circular Economy with lower production cost and more environmentally friendly. Ashes generated during the biomass combustion process are one of these by-products.

Currently, there is a growing interest in the valuation and recycling of waste and by-products throughout the world. The maximum reuse of any waste or by-product generated during an industrial process must have now a priority character. Among the most feasible alternatives at industrial level is the incorporation of these by-products as raw material in the manufacture of construction materials. Something that can contribute to reduce the risk of depletion of raw materials used by this industry, as well as to the called Circular Economy. In this way it is intended to make these industrial processes more sustainable and eco-friendly.

The most interesting wastes to be use as raw materials are the ashes of organic or biomass origin. It is due to their great generation, since at a global level, the increase that the use of biomass has had in recent years, as alternative energy source to those of fossil origin, has been spectacular.

In recent years, biomass energy has increased its use as alternative energy source. The conversion of biomass waste into energy can reduce their environmental impact. Several European directives such as 2009/28/EC of the European Parliament and of the Council ([European Parliament, 2009](#)) promote policies for the use of energy from renewable sources to reduce the net flow of greenhouse gases (CO₂) to the atmosphere ([Eliche-Quesada et al., 2017b](#)). However, it should also be noted that although this process of combustion of biomass in general is quite beneficial environmentally, also has some problems such as low combustion efficiency, high humidity and a high price of transport to the combustion site ([Batidzirai et al., 2013](#)).

In the world, large quantities of waste of agricultural origin are produced. Only in Europe, the amount of waste generated by agriculture is 250 million ton/year ([Setti and Ansaloni, 2005](#)). The waste to energy conversion processes for energy generation can have good economic and market potential. Biomass energy is an alternative source of energy compared to traditional sources of fossil such as coal and oil.

The large amounts of ash produced in biomass combustion process are an economic and environmental problem due to the high cost of storage, and management in landfills ([Chaunsali et al., 2018](#)).

When biomass is used as fuel to obtain electric and thermal energy, two types of ash are produced: bottom ash and fly ash ([Eliche-Quesada et al., 2017a](#)). Bottom ash constitute the unburned fraction produced on the boiler grate and in the primary combustion chamber and fly ash are carried with the flue gas and collected in cyclones and emissions control equipment (filters). The amount of bottom and fly and biomass ashes generated is about 480 million tons per year ([Modolo et al., 2014](#); [Vassilev et al., 2013](#)).

To close the circle and propose a Circular Economy, the use of biomass ash is proposed as a raw material to manufacture new materials, specifically for the construction sector.

Biomass ashes have been traditionally used as fertilizer ([Maschowski et al., 2016](#)). In recent years, the number of studies carried out for its reuse as raw material in construction materials has been important. Due to its proven pozzolanic activity, biomass ash is applied in the development of alkaline activated materials or geopolymers ([Peys et al., 2016](#); [Bonet-Martínez et al., 2018](#)), the manufacture of cement ([Yin et al., 2018](#)), concrete ([Lessar et al., 2017](#)), mortar ([Tosti et al., 2019](#)) or ceramic bricks ([Pérez-Villarejo et al., 2012](#); [Fernández-Pereira et al., 2011](#); [Cultrone and Sebastián, 2009](#)), and even as filler aggregate for bituminous mixtures ([Melotti et al., 2013](#)) and in general as binder raw material ([Chaunsali et al., 2018](#); [Hinojosa et al., 2014](#)).

The olive tree is one of the largest sources of biomass in Spain. Olive cultivation has a long tradition in the Mediterranean basin but also in other areas, such as South Africa, some areas of central Chile, California and southeastern Australia. At a global level, in 2016, the area dedicated to the cultivation of olive trees is almost 11,425 million hectares ([Vilar and Pereira, 2016/2017](#)), which indicates the economic importance for the world economy as well as the large amount of biomass waste generated by the processing necessary for the final transformation into olive oil.

Table 1 XRF composition of raw materials

Oxide content (wt%)	Clay	Olive biomass fly ash
SiO ₂	54.40	11.70
Al ₂ O ₃	12.36	2.51
Fe ₂ O ₃	4.58	1.26
CaO	8.76	10.20
MgO	2.46	3.03
MnO	0.03	—
K ₂ O	3.37	42.66
TiO ₂	0.60	0.11
P ₂ O ₅	0.11	2.97
SO ₃	0.68	3.60
ZnO	0.03	—
SrO	0.03	0.04
ZrO ₂	0.03	—
Cl	—	2.26
LOI	12.51	18.54

One of the great challenges that need to be addressed in terms of the valorization of olive biomass ashes is the great variability with respect to the types of plants used for incineration. It is also very seasonal, and this variability has a decisive influence on the chemical composition from the ashes. The chemical composition can also be affected by the transformations suffered in the combustion process at various temperatures to which they are subjected (Vassilev *et al.*, 2010). The mixture of burned biomass can also vary the composition of its ashes depending on the combustion technology used in different incineration plants. Chemically, olive biomass ash is basically composed of mineral oxides such as silica (SiO₂), alumina (Al₂O₃), calcium oxide (CaO) and carbon (C), which are also rich in potassium and unburned organic matter (Alburquerque *et al.*, 2004).

Ceramic materials, both for the mineralogical composition of the natural raw materials used for their shaping and the new minerals formed after their sintering-firing process, have a wide range of chemical and mineralogical composition. For this reason bricks can tolerate presence of different types of waste (Barbieri *et al.*, 2013). In this way part of the clayey raw Materials can be replaced by others that are currently considered industrial wastes. Although various studies have been made of the addition of biomass ash from different sources to building materials, few studies have been carried out using fly ash from the combustion of by-products of olive biomass (de la Casa and Castro, 2014; Eliche-Quesada and Leite-Costa, 2016).

On the other hand, construction sector consumes enormous quantities of raw materials, mainly clays. This new approach, where different percentages of raw materials are substituted by agro-industrial waste, can contribute to sustainability and prevent the depletion of natural resources.

In addition to this, it is noteworthy that the introduction of this type of waste decreases the thermal conductivity of the final material, thus it affects to energy savings. This fact is a key issue for the sustainability for the construction Materials.

This study aims to advance and deepen the recyclability of industrial waste by using it as a component to manufacture construction ceramic materials. Thus, fly ash was used from the combustion of the olive pomace, (a by-product of the olive oil production) as clay substitute raw material in the manufacture of ceramic bricks. The aim is to deepen in the characterization of the olive biomass fly ash (pomace) studying how different additions of waste (10–30 wt%) to clay pastes, as well as the firing temperature (900°C or 1000°C) modify the technological brick properties.

Materials and Methods

The raw materials used for this study were clay and fly ash from biomass of the olive grove (OBFA). The clay comes from Bailén quarries (Jaén, Spain), an industrial core for the manufacture of ceramic bricks, and the biomass ashes from the energy generation power plant of La Loma S.A., located in Villanueva del Arzobispo (Jaén, Spain).

Raw materials were characterized to know their mineralogical composition by means of X-ray diffraction (XRD) and its chemical composition by X-ray fluorescence (XRF). The characteristics of the equipment were the following: an X'Pert Pro MPD X-ray diffractometer from PANalytical and a Philips equipment model PW-2440.

Once the raw materials were characterized, clay and ashes were used to manufacture ceramic bricks with dimensions of 60 × 30 × 10 cm. 8 batches of 10 ceramic pieces each one were formed in a mold to be able to carry out all the technological tests proposed in the study, in which the percentage of ash was changed, replacing pure clay, 0 wt%, 10 wt%, 20 wt% and 30 wt%, and these percentages were made in duplicate in order to study two firing temperatures, 900°C and 1000°C. The batches were named 9C and 1C for the control bricks and the rest of batches with ashes added were named with 1 or 9 OBFAXX, being 1 or 9 the sintering temperatures and XX 10, 20 and 30 the content in weight% of olive biomass fly ash.

Fig. 1 XRD of olive biomass fly ash and clay.

Once the bricks were formed, and then characterized to determine their technological properties. The suction test was carried out according to the UNE-EN 772-11 standard (Spanish standard UNE-EN 772-11, 2011) and the absorption test with ASTM C373 standard (ASTM C373, 1994). For the measurement of the linear shrinkage, a calliper (accuracy of ± 0.01 mm) was used to determine the length of the ceramic samples before and after the firing process (ASTM C326, 1997).

Bulk density was calculated using the Archimedes method (ASTM C373, 1994). The tests of compressive strength were carried out according to the standard UNE-EN 772-1 (Spanish standard UNE EN 772-1, 2011) in a laboratory press MTS 810 Material Testing Systems. Prior to the breakage of the ceramic samples, the average surface of the two faces was calculated and the maximum load

reached between the average surfaces was divided and expressed with an accuracy of 0.1 MPa. Thermal conductivity of the bricks fired at 1000°C has been evaluated with a C-ThermTCi Analyzer with a universal sensor from Mathis Instruments Ltd.

Finally, the microstructure of the samples, once firing were studied using a High-Resolution Scanning Electron Microscope (HR-SEM) JEOL model SM 840, equipped with a device for measuring X-ray spectroscopy of dispersive energies (EDS) at 20 kV. In order to perform the EDS analysis on the samples, they were deposited with a carbon layer using a JEOL ion sputtering device, model JFC 1100.

Fig. 4 Water absorption and suction of ceramic bricks as a function of the olive biomass fly ash content at the two firing temperatures evaluated, 900 and 1000°C.

Results and Discussion

Raw Materials Characterization

Table 1 shows the values of the chemical composition, expressed in oxide form found in the raw materials by means of XRF. Clay has a chemical composition common to clays used in the manufacture of ceramic bricks with a preponderance of minerals rich in silica and alumina. Clay also has high values of calcium oxides in their composition, due to the presence of calcium carbonates (calcite). Regarding the chemical composition of olive biomass fly ash are rich mainly in potassium because it is the main component of pomace used as fuel. It has significant amounts exceeding 10 wt% of silica and calcium oxide, with amounts greater than 2% in SO_3 , MgO , P_2O_5 and Al_2O_3 . The high content of flux oxides, such as K_2O and oxides of auxiliary fluxes, such as CaO and MgO in the waste, fluxing facilitates firing at a lower temperature and introduces necessary elements for the formation of new phases.

Loss of ignition loss at 950°C of both the clay and the olive biomass fly ash may be due to a high content of organic matter (2.3 and 4.7 wt%), and mainly of carbonates (7.4 and 31.2 wt%) as well as the decomposition of inorganic compounds, such as SO_3 (0.7 and 1.3 wt%).

As regards the mineralogical composition of the clay (**Fig. 1**), associated minerals (quartz and calcite) and clay minerals as aluminosilicates are identified.

In the X-ray diffraction diagram of olive biomass fly ash (**Fig. 1**) it can be observed that there are hardly any crystalline potassium species. Considering that according to the data of XRF (**Table 1**) almost 43 wt% of the ash is composed of potassium oxide, it could indicate that potassium is forming part of amorphous species that are highly reactive and that will react with clay to form new mineralogical species to be sintered, acting mainly as fluxes and decisively influencing the porosity of the pieces. The crystalline mineralogical species observed in the XRD pattern are quite diverse, such as calcium silicates (CaSiO_3), magnesium (MgSiO_3 and Mg_2SiO_4) and calcium-magnesium (CaMgSiO_3), aluminum and potassium ($\text{K}_6\text{Si}_3\text{O}_9$), as well as species containing elements such as iron ($\text{Ca}_2\text{Fe}_2\text{O}_5$).

Characterization of Clay-Olive Biomass Fly Ash Bricks

During the firing process the dimensions and color variations take place in the bricks containing olive biomass fly ash. As can be seen in **Fig. 2**, bricks change color both by adding different amounts of ashes and with the firing temperature, having a more yellowish color at firing temperatures of 1000°C. In the bricks no defects were observed as cracks, the defect known as black heart due to incomplete combustion of organic matter or efflorescences after the firing process. Different technological properties of the fly ash bricks of olive and clay biomass compared to the control brick (containing only clay) were studied.

The linear shrinkage of the bricks reflects the expansion/contraction behavior during the thermal firing treatment. In **Table 2** it can be seen that the linear shrinkage of the control bricks fired at 900 and 1000°C was -0.52% and -0.38% , respectively. The addition of increasing amounts of biomass fly ash produces an increase in linear shrinkage. Therefore, the control samples, such as the samples containing olive biomass fly ash, expand slightly during the firing process. This expansion could be due to the gases released during the firing process due to combustion of the organic matter and the decomposition of the carbonates contained both in the clay and in the residue (fly ash).

Fig. 5 SEM micrography and EDS analysis of ceramic samples: (a) Clay at 900°C, (b) clay at 1000°C, (c) 9CFA10, (d) 9CFA30, (e) 1CFA10, and (f) 1CFA30.

Clay control bricks have the lowest loss on ignition when firing at 900 and 1000°C (9.2% and 13.2%, respectively). The addition of fly ash increased the loss of ignition to greater addition of waste and higher sintering temperature. The increase observed in the weight loss on ignition could be due to the greater amount of organic matter and the higher content of carbonates present in the olive biomass fly ash.

Fig. 3 shows the variation of the compressive strength of the ceramic samples manufactured as a function of the percentage by weight of fly ash added to the clay at the firing of 900 and 1000°C. The mechanical strength depends on the

Fig. 5 Continued

microstructure of the pieces, such as porosity, microcracks and also on the phase changes produced during the firing process (Vieira *et al.*, 2005). The substitution of clay by ashes produces a decrease in the compressive strength at both firing temperatures. This loss in the mechanical properties as increasing amounts of fly ash residue in the samples could be due to the increase in porosity, as indicated by the decrease in bulk density (Table 2). Pores and other imperfections act as concentrators of tensions, decreasing the resistance to compressive strength. As for the influence of the firing temperature, an increase in the mechanical resistance of the ceramic bricks firing at 1000°C is observed due to the greater degree of densification achieved. Ceramic bricks fired at 1000°C present higher apparent density values. The densification is achieved by the viscous flow of a sufficient amount of liquid phase to fill the spaces occupied by the pores between the solid grains, due to the tensile forces of the surface. During cooling, the molten phase solidifies and the vitreous matrix favors the formation of a more resistant and dense structure (Eliche-Quesada *et al.*, 2017b). The compressive strength value for pure clay samples at 900°C is 53.39 MPa and from this value, increasing the ash replacing percentage, the values of mechanical resistance are gradually decreasing, reaching the minimum value, 33.07 MPa for a 30 wt% substitution, which means a fall of almost 40%. For the case of pieces fired at 1000°C, the reduction from 55.06 MPa for pure clay to the minimum value, those pieces containing 30 wt% ash, 34.70 MPa, which means a drop of 37%. This lower fall of the mechanical strength values indicates that the degree of sintering and therefore of densification, reached for the pieces at 1000°C is higher than those of 900°C. On the other hand, the development of crystalline phases at higher temperatures could lead to the production of products with greater mechanical resistance, such as tridymite, the intermediate temperature phase of silica. According to the regulations applicable to ceramic construction bricks (Annex, 2008), the values reached by ceramic bricks must be at least 9.8 MPa. So all the series obtained in this study meet this requirement.

In Fig. 4, water absorption and water suction of the firing samples fired at 900 and 1000°C respectively can be observed. The water absorption is related to the open porosity developed during the firing process. It decreases with increasing sintering temperature from 900 to 1000°C, likewise increases in both series as the fly ash increases. The decrease in the water absorption with the firing temperature has been observed previously by other authors (Lessar *et al.*, 2017). This decrease is related to the formation of a greater quantity of vitreous phase at a higher firing temperature, obtaining a denser microstructure that closes the pores and their interconnections. As pointed by Romero *et al.* (2008), the generation of liquid or amorphous phase causes the particles to approach each other and generates a smaller volume of pores. Consequently the porosity must decrease. Another aspect to take into account is the presence of fluxing agents such as potassium, magnesium, sodium and calcium. According to the chemical composition of the fly ash (Table 1), the sum of flux oxides and auxiliary flux oxides in the ash is almost 56%. So increasing its content in the clay the structure should be denser, with less open porosity. However, the observed effect is opposite, since there is an increase in water absorption and a decrease in bulk density. This could be due to the fact that at both sintering temperatures, the viscosity of the liquid phase allows the decomposition of the gas phases. The waste, fly ash, presents a higher

Fig. 6 (a) Thermal conductivity of the bricks fired at 1000°C and (b) Relationship between the thermal conductivity and the bulk density of the ceramic pieces.

content in organic matter and, especially, of calcite greater than in the clay, generating CO_2 during the firing process that remains trapped, generating porosity in the pieces.

The suction of water is related to the interconnected surface porosity and its value depends on the union of the brick and mortar and the water retention of the mortar. Low water suction values are preferred. This would indicate that the brick does not absorb a large amount of water. It leaves enough mortar for the mortar to harden at a speed that allows the correct adhesion of the bricks with the mortar. As can be seen in Fig. 5, the water suction for the control bricks fired at 900 and 1000°C was 0.23 and 0.22 g/cm² min respectively. The water suction is slightly increased when larger amounts of waste fly ash are added. This increase is being more pronounced in the bricks fired at 900°C. Thus the water suction increases from 0.26 to 0.28 g/cm² min with the addition of 10 and 30 wt% of OBFA in the bricks fired at 900°C and from 0.22 to 0.25 g/cm² min for the bricks fired at 1000°C. The increase in water suction could be due to an increase in interconnected surface porosity at higher fly ash content and lower sintering temperature due to pore growth, both in number and size, caused by the largest amount of organic matter and carbonates in the waste. The regulations applicable to this test mark the maximum admissible value for ceramic pieces 0.45 g/cm² min. None of the ceramic clay bricks containing waste exceed the limit value. However, when presenting values higher than 0.15 g/cm² min, the bricks should be moistened before they are placed to achieve an adequate bond between the brick and the mortar.

The microstructure and porosity of the control bricks and bricks containing olive biomass fly ash after the firing process were studied by SEM-EDS. Fig. 5 shows some details of the fracture surface of different ceramic pieces studied, control pieces and pieces containing 10 and 30 wt% of OBFA fired at 900 and 1000°C. In the micrographs a morphological and compositional heterogeneity of the samples as well as the present porosity can be appreciated. It is known that the morphology of the pores influences the mechanical properties exhibited by the materials. In this context pores with angled shape act as stress concentrators, thus

reducing their mechanical resistance. Concerning the influence of firing temperature, a greater concentration of angular pores can be observed in the samples fired at 900°C. However, as the firing temperature increases up to 1000°C sintering increases and it is promoted that a greater proportion of liquid phase is formed. This effect generates greater closed porosity and modifying the shape of the pores, observing more rounded pores.

In relation to the influence of the residue content, it is observed at the two firing temperatures, a low degree of densification, lower at lower firing temperature. It is obvious the presence of open porosity, the higher is the higher is the incorporation of residue. Open porosity is largely responsible for the decrease in compressive strength as the percentage of ash replaced by clay increases. Some areas were analyzed by EDS microanalysis, showing that there are zones with the presence of the typical minerals of the ceramic materials, such as aluminosilicates. It is confirmed by the presence of some cations, for instance Ca, Mg, K and Fe (Fig. 5(c-f)), which agrees with the elemental analysis found by XRF (Table 1) and the mineralogy by XRD (Fig. 1). The micro-analysis also shows areas where the presence of fly ash added, as in Fig. 5(d and f) where there is a strong presence of K and Ca. These components are identified coming from the ashes.

The thermal conductivity of the bricks fired at 1000°C has been determined. Thermal conductivity is an important property, since an increase in the thermal insulation of bricks can lead to significant energy savings in buildings. The thermal conductivity of the control bricks was 1.05 W/mK (Fig. 6(a)) reducing the value of thermal conductivity to 0.82, 0.80 and 0.69 W/mK with the addition of 10, 20 and 30 wt% of olive biomass fly ash. This value indicates that the incorporation of 10, 20 and 30 wt% of ashes produces a decrease of 21.9%, 23.8% and 34.3%, respectively. So, the use of bricks incorporating fly ash as structural elements in the building would produce significant energy savings. A linear relationship between thermal conductivity and the bulk density of the fired ceramic pieces at 1000°C has been found (Fig. 6(b)). The regression analysis shows a coefficient of $R = 0.8531$.

Conclusions

This study has demonstrated the feasibility of using fly ash from olive groves as a substitute for raw material for the manufacture of ceramic bricks, with similar characteristics in quality to those made with pure clay, which served as control for the study. Ceramic bricks were produced by adding percentages of ash substitution between 0 and 30 wt% and fired at two different temperatures: 900 and 1000°C. The following conclusions of this study can be established, as follows:

Compressive strength of the ceramic brick decreased with increasing replacement of clay by fly ash. This occurs due to the increased porosity generated in the pieces during firing, as indicated by the decrease in bulk density. Ceramic bricks fired at 1000°C present bulk density values higher than 900°C and therefore better mechanical performances. On the other hand water suction is slightly increased when larger amounts of olive biomass fly ash are added.

From the microstructural point of view, the morphology of the pores influences the mechanical properties exhibited by the materials. Pores with an angular shape act as tension concentrators, thus reducing their mechanical resistance. The fired samples at 1000°C had a lower concentration of angular pores of this type than those of 900°C. It can be concluded that also at 1000°C the samples had a greater proportion of liquid phase, generating greater closed porosity, increasing the bulk density and increasing the mechanical resistance.

Finally, the thermal conductivity of the control bricks was 1.05 W/mK and the samples with 30 wt% of fly ash fired at 1000°C showed a 34.3% reduction, which would produce an important energy saving in the studied samples.

Acknowledgments

This work has been funded by the Project "Valuation of various types of ash for the obtaining of new sustainable ceramic materials" (UJA2014/06/13), Own Plan University of Jaén, sponsored by Caja Rural of Jaén. The authors thank to the company "Energía de la Loma S.A." for supplying the ashes. Technical and human support provided by CICT of Universidad de Jaén (UJA, MINECO, Junta de Andalucía, FEDER) is gratefully acknowledged.

Introduction

Crude oil has been the source of chemicals often used as monomers to form commercial polymers for many decades. Since 1907, when the first synthetic polymer (Bakelite) was prepared by Leo Baekeland, great advancements have been made in the polymer field. In spite of its widespread use, the finite nature of crude oil poses a fundamental challenge for its continuous use. It has become obvious that mankind needs alternative resources to attain a sustainable lifestyle in industrialized countries (Rudolph, 2018). In that context, vegetable oils offer a renewable feedstock that can be used as a substitute of petroleum-based chemicals in various applications, including transportation fuels and polymers.

Vegetable oils are easily extracted from plants, hence their abundance and renewable nature. Different plants naturally produce different oils, with a different chemical structure and different properties. Therefore, a great variety of materials can be prepared from vegetable oils. Despite the great variability found in vegetable oils from different plants, the vegetable oil produced by any given plant species is very consistent, making vegetable oils a very reliable renewable resource for the preparation of polymers. In this text, the term “vegetable oil” is used in reference to triglycerides. Triglyceride oils have been heavily investigated as the source of various monomers for the preparation of bio-based polymers. Bio-based polymers are defined as any type of polymeric substance produced from renewable resources of biological origin. Fig. 1 presents the structure of a triglyceride, as well as other molecules directly derived from it.

The use of renewable resources in replacement of petroleum is justified by the need of reducing carbon footprint. Indeed, when a renewable raw material, such as vegetable oils, is employed in the fabrication of plant-based biopolymers, a neutral carbon footprint is achieved since the plants harness carbon from the atmosphere in the form of CO₂ in order to produce the oils, which are then converted into polymers and composites. This contrasts with the free “generation” of carbon when petroleum-based monomers are used instead.

Fig. 1 Chemical structure of (a) soybean oil triglyceride, (b) glycerol, (c) linoleic acid, an example of a fatty acid, (d) soybean oil half ester, (e) soybean oil monoglyceride.

In this text, the major classes of vegetable oil-based polymers are discussed. Emphasis is given to polyolefins from unmodified oils, polyurethanes, and polymers from maleated oils and half-esters. Other approaches, such as the ring-opening of caprolactones, olefin metathesis, and polyester resins are also briefly covered. The reinforcement of these systems with natural and inorganic materials to generate bio-based composites of relevant properties is systematically addressed before concluding with a perspective of current commercial applications of vegetable oil-based polymers and composites.

Vegetable Oil-Based Polymers

Polyolefins

Within the last decade, various vegetable oil-based co-polymers with a range of thermal and mechanical properties were prepared from the free radical or the cationic co-polymerization of triglycerides with reactive petroleum-based comonomers. In such systems, the carbon-carbon double bonds constitute reactive sites, which can be enhanced when they are conjugated (Fig. 2; Xia *et al.*, 2013).

The low reactivity of regular vegetable oils towards free radical or cationic polymerizations limit their direct use (without chemical modification) for the preparation of bio-based polymers. Drying oils have been historically used in paints and coatings. The spontaneous auto-oxidation of such oils under air leads to a crosslinked polymer network with interesting properties. Following a similar approach, co-polymers containing vegetable oils can be prepared by free radical polymerization. For example, 30–65 wt% of unmodified linseed oil has been free radically co-polymerized with styrene (ST), and divinylbenzene (DVB) to form thermosetting polymers with mechanical properties that vary depending on the oil content. Along the same lines, 30–70 wt% of unmodified tung oil was copolymerized with ST and DVB in the absence of free radical initiators to yield materials ranging from elastomers to rigid polymers, with glass transition temperatures (T_g) of -2 to 116°C and crosslink densities of 1.0×10^3 – 2.5×10^4 mol/m³. The monomer mixture was simply heated at 85 – 160°C . It was found that the addition of catalytic amounts of Co, Ca, and Zr salts increases the thermal polymerization rate and results in thermosets with improved properties (Xia *et al.*, 2013). Indeed, tung oil consists of 84% of α -eleostearic acid (a naturally conjugated fatty acid), totaling an average of 9.0 carbon-carbon double bonds per triglyceride, and making tung oil readily polymerizable under mild conditions.

Conjugated triglycerides are more reactive towards free radical polymerization than non-conjugated triglycerides. Therefore, conjugated oils are most commonly used for the preparation of vegetable oil-based polymers. The conjugation of carbon-carbon double bonds in triglycerides can be easily accomplished with the use of a rhodium catalyst (Quirino and Larock, 2012a). Translucent thermosets have been prepared from the bulk free radical polymerization of 30–75 wt% of conjugated linseed oil (CLO), acrylonitrile (AN), and DVB. The thermal, physical, and mechanical properties of these materials decrease with increases in the vegetable oil content. Also, the percentage of unreacted oil in the final polymer ranges from 4 wt% to 39 wt% and is directly dependent on the amount of oil employed. Several other conjugated oils have been used for the preparation of bio-based polymers using a similar approach, however when an oil that is less reactive than TUN is used, a microphase separation is typically obtained (Xia *et al.*, 2013).

Vegetable oil-based thermosetting materials can also be obtained via cationic polymerization of triglycerides in the presence of other reactive co-monomers. Similarly to the free radical polymerization, strong materials with room temperature storage modulus of ~ 2 GPa can be obtained by the cationic copolymerization of 50–55 wt% of TUN with DVB. Blends of TUN and other oils with a lower degree of unsaturation, such as soybean oil (SOY), can be used to achieve desired polymerization rates. Poor miscibility between the oil and the cationic initiator (BF_3) results in micro-phase separation with distinctly different crosslink densities in different parts of the bulk copolymer. Modification of BF_3 with less reactive oils helps to ensure formation of more homogeneous vegetable oil-based polymers. Other oils used for cationic polymerization include regular and conjugated corn oils, olive, peanut, sesame, canola, grapeseed, sunflower, safflower, walnut, and linseed oils. The cationic polymerization of soybean oil with 4-vinylphenyl boronic acid or 4-trimethylsilylstyrene afforded boron- or silicon-containing thermosets with flame retardant properties. Also, uniform bio-based cationic polymers have been obtained from the copolymerization of Dilulin and ML189 (pericyclic products of linseed oil and cyclopentadiene) with dicyclopentadiene (Xia *et al.*, 2013).

More recently, less common oils have been used as monomers for the preparation of bio-based polymers. For example, the oil extracted from the seeds of *Vernonia galamensis* was directly polymerized using fluorosulfonic acid as a catalyst. The resulting polymer ranged from a viscous oil to an insoluble resin, depending on the amount of catalyst used (Biswas *et al.*, 2014). A variety of plant oils were also polymerized using triazolidinedione, yielding polymers with gel times in the 2–8 min range (Türünç, 2015). Along the same lines, the oil of the *Ricinodendron heudelotii* plant was also photopolymerized with and without a photoinitiator under UV radiation (Assanvo *et al.*, 2015).

Fig. 2 Simplified reaction scheme showing the conjugation of carbon-carbon double bonds in soybean oil.

Polyurethanes (PUs)

Due to its natural hydroxyl groups, castor oil has been widely used in the synthesis of vegetable oil-based polyurethanes. Indeed, castor oil (**Fig. 3**) is formed of approximately 90% of ricinoleic acid. Thermosetting PUs with good thermo-mechanical and swelling properties have been obtained from the reaction of castor oil with diisocyanates, such as toluene diisocyanate, isophorone diisocyanate, and hexamethylene diisocyanate. Other approaches involve blending castor oil and poly(ethylene glycol) during the synthesis of PUs. Such materials have shown potential for use as biomedical implants and for tissue engineering (Xia *et al.*, 2013).

The carbon-carbon double bonds in other vegetable oils can be converted into hydroxyl groups, therefore providing a great variety of renewable polyols for the preparation of bio-based PUs. Following that approach, PUs with different crosslink densities have been prepared from rapeseed, palm, canola, soybean, sunflower, corn, and linseed oils. Soybean oil-based polyols with hydroxyl numbers ranging from 82 mg KOH/g to 225 mg KOH/g have been used in the preparation of PUs ranging from brittle to rubbery. In the preparation of polyols from epoxidized vegetable oils, different nucleophiles, such as lactic acid, diethylene glycol, hexamethylene glycol, methanol, glycerol, and 1,2-propanediol can be used to carry-out the ring-opening reaction (**Fig. 4**; Xia *et al.*, 2013).

A polyol from carbonated soybean oil (**Fig. 5**) has been obtained by a ring-opening reaction with ethanolamine. This polyol was condensed with polyisocyanates to generate thermal and electrical insulating PUs. Another approach towards vegetable oil-based polyols consists in the hydroformylation of carbon-carbon double bonds, resulting in aldehydes that can be subsequently reduced to primary alcohols. These polyols have been reacted with MDI to obtain polyurethane thermosets with different crosslink densities. The ozonolysis of canola oil has led to polyols used for the preparation of PUs with 1,7-heptamethylene diisocyanate (Xia *et al.*, 2013).

Waterborne anionic polyurethane dispersions (PUDs) have been prepared by dispersing a PU formed from the reaction of soybean oil polyol and isophorone diisocyanate with deprotonated dimethylolpropionic acid (DMPA). The Young's modulus of corresponding dry films ranged from 8 to 720 MPa, while the tensile strength ranged from 4.2 to 21.5 MPa, and the elongation at break varied from 16% to 280%. In a similar approach, cationic PUDs were obtained simply by replacing DMPA with protonated

Fig. 3 Chemical structure of castor oil.

Fig. 4 Simplified reaction scheme of the ring-opening of epoxidized soybean oil with methanol.

Fig. 5 Chemical structure of carbonated soybean oil.

N-methyl diethanol amine (MDEA). PU-silica nanocomposite dispersions were prepared by grafting silica nanoparticles to the PU chains, resulting in an overall improvement of thermal and mechanical properties (Xia *et al.*, 2013).

Alternative vegetable oils, such as jatropha oil, were recently used for the preparation of polyols through epoxidation followed by oxirane ring-opening. The polyol obtained was reacted with isophorone diisocyanate and DMPA to form an aqueous polyurethane dispersion (Saalah *et al.*, 2017). In a differently approach, non-isocyanate PUs can be prepared from cyclic carbonates derived from glycerol, which forms the backbone of triglyceride oils. Glycerol can be easily converted into glycerol carbonate. A variety of cyclic carbonates have been prepared from glycerol and subsequently reacted with a range of amines to yield polyhydroxyurethanes through ring-opening polymerization (Johns *et al.*, 2016).

Acrylated/Maleated Oils and Half Esters

The carbon-carbon double bonds in unsaturated vegetable oils can be chemically modified for the incorporation of acrylates. Acrylated epoxidized soybean oil (AESO) has been copolymerized with ST, resulting in structural thermosetting materials. Likewise, acrylated epoxidized methyl oleate has been prepared by the same method and used in the preparation of a bio-based polymer by free radical emulsion polymerization. An alternate route for the preparation of acrylated triglycerides consists in the oxidation of unsaturated vegetable oils with singlet oxygen to form hydroperoxides, which can then be converted into secondary allylic alcohols, followed by further reduction of residual carbon-carbon double bonds. These alcohols can be easily functionalized with acrylate groups, which serve as monomers for free radical polymerization, resulting in materials with similar properties to those of AESO-based materials. Maleated epoxidized soybean oil (MAESO) is obtained by the reaction of AESO with maleic anhydride (MA). When MAESO is copolymerized with ST, higher crosslink densities, T_g 's, and storage moduli than the corresponding AESO-based polymers are obtained (Xia *et al.*, 2013).

Besides modification of the carbon-carbon double bonds, chemical changes involving the ester groups of vegetable oils is another viable method for the preparation of triglyceride-based polymers. A series of rigid thermosetting polymers with T_g of 135°C and storage modulus of 0.92 GPa at 35°C have been prepared via bulk copolymerization of soybean oil monoglyceride (SOMG – Fig. 1) maleates with ST. An increase in the properties of the SOMG maleate-ST polymers has been observed when neopentyl glycol and bisphenol A were added to SOMG prior to the reaction with MA. The same methodology has been applied to linseed, and castor oils, with improved properties (Xia *et al.*, 2013). On a different approach, tung oil was used to synthesize a co-ester containing acrylates and maleates. This co-ester was copolymerized with ST to produce a rigid material with a tensile strength of 36.3 MPa and a Young's modulus of 1.70 GPa (Liu *et al.*, 2016).

Other Approaches

In previous sections, polyurethanes, polyolefins, maleated oils and half esters synthesis methods and properties were discussed. In this section, ring-opening metathesis polymerization (ROMP), acyclic diene metathesis (ADMET) polymerization, mechanisms involving polyesters such as condensation polymerization, polyamides, and other commonly utilized polymerization methods will be discussed. Olefin metathesis methods originate back to the 1960s and has hence forth paved the way for the currently utilized, highly reactive, metal alkylidene catalysts. These carbene complexes of transition metals are reactive enough to interact with most functional groups, while maintaining stability when exposed to air or moisture. These catalysts are crucial in the following two polymerization mechanisms, ROMP and ADMET.

Monomers applicable for ROMP mechanisms are strained, unsaturated cyclic hydrocarbons such as norbornene groups (Fig. 6). These strained rings are catalyzed with a ruthenium carbene catalyst to break the carbon-carbon double bonds. Castor oil, a vegetable oil containing approximately 85%–90% ricinoleic acid, polymerized with bicyclo[2.2.1]hept-5-ene-2,3-dicarboxylic anhydride, produces a functionalized bicyclic castor oil derivative (BCO). The BCO derivative and cyclooctene can be co-polymerized to yield a co-polymer with elastomeric properties. BCO, as do other vegetable oil derivatives, exhibit high viscous characteristics due to their low glass transition temperatures (T_g 's) (Henna and Larock, 2007). Which inherently creates a co-polymer weight percentage threshold for the polymerization to materialize. As expected, there is a direct correlation between the percentage of unreacted triglycerides and the thermal stability in the final polymer.

The majority of reactions involving vegetable oils occur at the ester group due to its inherent reactivity (Armylisasa *et al.*, 2017). Acyclic Diene Metathesis (ADMET) is a derivative of cross-metathesis in which dienes produce linear polymers by step-growth kinetics, with the production of ethylene as a by-product. Since ADMET is a reversible process is, ethylene must be removed to

Fig. 6 Chemical structure of norbornene.

favor polymerization. One significant application of this versatile polymerization mechanism is in the production of dendrimers. Recently, di(trimethylolpropane)tetra-acrylate and dipentaerythritol hexa-acrylate core units, and a fatty acid-derived 10-undecenyl acrylate monomer were prepared for post-polymerization via a base-catalyzed Thiol–Michael addition to create a hyper-branched dendrimer (Unverferth and Meier, 2014). Additionally, under this mechanism, bio-based polymers ranging from tacky oils to elastomeric materials have been polymerized utilizing Grubbs 1st generation catalyst and soybean oil. Furthermore, undec-10-enyl undec-10-enoate, vinyl dienes derived from plant oils, generated highly crosslinked block co-polymers under ADEMT conditions. These co-polymers can easily be manipulated to suit multiple applications by simply altering the amount of monomer and chain stopper used in the synthesis (Murawski and Quirino, 2018).

Internal carbon–carbon double bonds, and ester groups are pivotal in the activation of many polymerization reactions. In regards to condensation polymerization, the reaction does not respond to internal carbon–carbon double bonds, such as free radical or ionic polymerization. Instead, the ester bond is broken to yield glycerol and the respective fatty acids. Although, the unsaturations in vegetable oils are often converted into polyols prior to polymerization. Condensation polymerization is commonly used in the preparation of polyesters and polyamides from vegetable oils. There are several successful methods for the synthesis of polyesters from vegetable oils, such as transesterification, acylation, condensation of dicarboxylic acids and anhydrides, and ring-opening of lactones. Nahar seed oil was reacted with glycerol under alcoholysis conditions to produce polyols, which then underwent esterification with acid anhydrides. These newly formed polyester resins were found to have a high resistance to harsh solutions such as dilute, strong acids, and aqueous NaCl solutions, making these polymers optimal for coating applications. Soybean oil with maleate grafted residues allow vegetable oil derivatives to polymerize with polyols and yield crosslinked thermosets. These thermosets have a wide spectrum of applications, highly dependent on the polyol and oil utilized in the polymerization reaction. Similar materials prepared from castor oil have resulted in flexible thermosets with low T_g s and comparable mechanical properties to that of commercially available polyurethanes. Despite an observable decreased hardness in comparison to their petrochemical analogues, these bio-polymers could be used as efficient sealants on account of their increased elasticity (Murawski and Quirino, 2018).

Polyamides are formed from the condensation of diamines and dicarboxylic acids, with water as a by-product. In fact, polyesteramides have been synthesized by curing ethylenediamine tetra acetic acid (EDTA) with linseed oil, poly(styrene-*co*-maleic anhydride) at ambient temperature for applications in coatings based on its decomposition resistance and physico-mechanical properties. A castor oil amide derivative (N,N'-bis(2-hydroxyethyl) anhydride) was subjected to condensation polymerization with diethanolamine to produce a hyper-branched polyesteramide with promise for applications as surface coatings. Long chain polyesters and polyamide vegetable oil derivatives have been the center of recent attention and have been suggested as suitable bio-based replacements for polyethylene. Many advantageous qualities arise from these polymers such as increased hydrophobicity, as well as increased structural stability (Zhang *et al.*, 2017). Block co-polymers were also synthesized by the polymerization of soybean oil-based dicarboxylic acids, diamines and amino acid monomers. As expected, the type of amino acid monomers utilized in the polymerization reaction determined the chain structure and crystallinity of the cured polyamide co-polymer (Murawski and Quirino, 2018).

Composites

The polymers mentioned in Section “Vegetable Oil-Based Polymers” have been reinforced with natural fibers and inorganic materials to generate a series of bio-based composites suitable for structural applications. For example, cationic copolymers of corn oil, ST, and DVB have been successfully reinforced with up to 45 wt% of glass fibers, resulting in significant improvements in Young’s modulus and tensile strength. The use of conjugated corn oil in replacement of regular corn oil results in a material with overall improved properties. Likewise, soybean oil-based cationic polymers have been reinforced with up to 50 wt% of glass fibers, leading to significant increases in Young’s modulus and tensile strength. Glass fibers were also used as reinforcement in ROMP copolymers of dicyclopentadiene (DCPD) and dilulin, resulting in a significant increase in Young’s modulus (Quirino *et al.*, 2014).

Another reinforcement studied for the preparation of vegetable oil-based composites is montmorillonite. Indeed, cationic thermosetting copolymers from conjugated soybean oil showed intercalated and exfoliated clay morphology for loadings of 1–2 wt%. Similarly, montmorillonite was used as a reinforcement in corn oil-based composites, resulting in an improvement in mechanical properties. In that system, optimum properties were obtained for clay loadings of 2–3 wt% (Quirino *et al.*, 2014).

Bio-based composites with a biorenewable content of up to 95 wt% have been prepared by reinforcing vegetable oil-based thermosetting resins with corn stover, wheat straw (Quirino *et al.*, 2014), spent germ (Pfister *et al.*, 2008), soybean hulls (Quirino and Larock, 2009), rice hulls (Quirino and Larock, 2011), wood flour (Quirino *et al.*, 2012b), oat hulls (Quirino *et al.*, 2012a), and sugar cane bagasse (Quirino and Larock, 2012b). In these composites, the polymerization had to be carried-out through a free radical process because the ligno-cellulosic fillers rapidly quench strong Lewis acids typically used for cationic polymerization. During compression molding, the presence of ligno-cellulosic filler particles minimize shrinkage of the resin, limiting the formation of micro-cracks (Quirino *et al.*, 2014). In order to improve mechanical properties, recent studies of natural filler-reinforced composites suggest that MA (Quirino *et al.*, 2012b), and asolectin are good filler-resin compatibilizers (Johns *et al.*, 2015).

Spent germ of different particle sizes was used to reinforce a tung oil (TUN)-based resin, resulting in an increase in storage modulus. The incorporation of shorter particles and higher DVB content also resulted in an overall improvement of the material’s properties. When the filler load was increased from 40 wt% to 60 wt%, agglomeration and formation of micro-voids in the

Table 1 Maximum mechanical properties obtained for selected vegetable oil-based resins and composites

composite caused an overall decrease in mechanical properties. It was also found that residual corn oil from the spent germ acted as a plasticizer in the composite. Removing the oil prior to impregnation of the fillers resulted in better mechanical properties (Pfister *et al.*, 2008). In a conjugated soybean oil-based free radical resin reinforced with soybean hulls, when BMA or DVB were substituted with dicyclopentadiene, the mechanical properties were compromised. The different reactivities of the comonomers used to form the matrix resulted in a micro phase-separation (Quirino and Larock, 2009).

When using rice hulls as reinforcement, it was observed that composites prepared with conjugated linseed oil exhibited better overall properties than those prepared from conjugated soybean oil due to the higher degree of unsaturation of the former (Quirino and Larock, 2011). A thorough study on the effects of different natural oils and different natural fillers on the properties of cationic composites was also carried out. Cationic resins made from conjugated soybean, linseed, and corn oils were reinforced with corn stover, wheat straw, and switch grass. Among the fillers evaluated, wheat straw afforded the most promising composites (Quirino *et al.*, 2014). Recently, resins produced from epoxidized acrylated sunflower seed oil copolymerized with ST in the presence of boron trifluoride were reinforced with short fibers of Alfa plant. It was found that 7.5 wt% of Alfa fibers treated with 5% NaOH produced sunflower seed oil composites with best mechanical properties (Kadem *et al.*, 2018). In another study, epoxidized soybean oil reacted with acrylic acid, then with maleic anhydride, was blended with 33 wt% ST. Cetyltrimethylammonium bromide-modified bentonite was added to the resin via compression molding. After testing, soybean oil-based composites with 3 wt% of modified bentonite exhibited the best mechanical properties (Mandal *et al.*, 2018). **Table 1** presents a comparison of the maximum mechanical properties obtained for some selected vegetable oil-based unreinforced resins and composites prepared from the same oils.

Conclusions

In an effort to cover the main advancements in the synthesis, properties, and applications of vegetable oil-based polymeric materials in a concise way, this text covered various types of bio-based resins, including those from polyolefins, polyurethanes, acrylated/maleated oils and half-esters, along with some other relevant approaches. All of these systems have been reinforced with inorganic materials and natural fibers to generate vegetable oil-based composites exhibiting promising properties.

Public pressure and government-driven initiatives pushing for more sustainable commercial practices have incentivized companies to seek ways to reduce their impact on global ecosystems. As the majority of plastics in current commercial use are non-biodegradable and/or from non-renewable origins, reducing the impact of plastics on the environment presents a potential approach. One of the main alternatives for the preparation of polymers with a lower environmental impact is the use of vegetable oils as a building block. Indeed, vegetable oils are widely available natural resources that have been a subject of great interest in polymer research over the past few decades. With the market for bioplastics expected to increase in the foreseeable future, it is important to understand the role that vegetable oil-based polymer applications play in that context.

It is worth noting that, in many cases, the positive environmental impact of polymeric materials prepared from renewable resources is more related to their sustainable nature than to biodegradability and recyclability aspects. In fact, there are very few studies on the biodegradability of the systems presented here. From a chemistry stand point, the highly crosslinked systems typically prepared from unsaturated vegetable oils represent a recycling challenge. Some new recycling approaches are currently under investigation, but no concrete progress has been reported to date. The breakdown of biocomposites can be facilitated by swelling and water absorption of the natural fibers commonly used as reinforcement, but the biodegradation of the polymer

matrix hasn't been extensively investigated. When considering sustainability aspects, however, the use of biorenewable building blocks, such as vegetable oils, promotes a better balanced carbon cycle, since the carbon source of the renewable monomers is ultimately atmospheric CO₂ captured by plants during photosynthesis and eventually incorporated into vegetable oils. Therefore, the use of biorenewable monomers results in a virtually neutral carbon footprint, as opposed to polymers derived from petroleum, which in net terms, introduce more C into the carbon cycle.

The use of vegetable oils has been encouraged in efforts to address the concerns that have arisen from the increased manufacturing and disposal of petroleum-based plastics. Vegetable oil polymers are becoming more commonly used to produce plastic applications such as packaging, hot-melt adhesives, coating applications, inks, among other diverse uses. The current investigation of new methods for the production of tires has seen the use of vegetable oil-based polymers as a potential alternative. The use of vegetable oils in paint coatings represents an advancement in the replacement of petroleum-based chemicals previously used.

Research into the reinforcement of composites from these materials has investigated the use of natural fibers to provide properties that render them more suitable for commercial use. In view of these current trends, vegetable oil polymers seem to show promise for future development; and while these materials show the potential to have a lower environmental impact than petroleum-based products, more information is still required to achieve a full understanding of their entire cost, from both economic and environmental standpoints.

Introduction

Recycling is an activity that has been carried out in the biosphere as an inseparable part of biological processes since the beginning of time (Sidiq *et al.*, 2010; Botetzagias *et al.*, 2015). A leaf that falls, a tree that burns, or an animal that dies and, in general, all the events that happen in nature, end up becoming part of the biochemical, physical, or geological processes maintaining the balance and sustainability of ecosystems.

As humankind has become independent from the biological processes of the biosphere, it has increased its capacity to transform the environment, introducing new and differentiated systems and elements as a result of that capacity for transformation acquired over millions of years of evolution.

Metallurgy, agriculture, animal husbandry, the development of cities, the manufacture of textiles, the discovery of paper, and many other milestones in the history of humanity have introduced elements processed through techniques and “artificial” methods that are not easy to integrate into the natural cycles of the biosphere.

Today, cities and their surrounding activities generate thousands of tons of waste that, without recycling, ends up in landfills (Zaman and Lehmann, 2011). Recycling involves the reuse of different types of items and objects that would otherwise be discarded, contributing to a larger amount of waste and ultimately continuously damaging the planet, making it an act of vital importance to society. Recycling refers to an act by which an object that has already been used is carried through a renewal process rather than being discarded. Experts in the field consider that almost all the elements that surround us can be recycled or reused in different situations, although some of them, because they are extremely toxic, cannot be conserved (Westkämper and Warnecke, 2010).

The current model of production and management of resources, goods, and services seeks to promote consumption in the short term and this pushes the planet into an unsustainable situation. The concept of sustainability includes the circular economy, which proposes that waste produced by industry, municipalities, services, etc., can be valued and transformed into new materials (Geissdoerfer *et al.*, 2017). Thus, the circular economy is presented as a system of resource utilization where the reduction of elements is a priority: Minimize production to the minimum indispensable, and when it is necessary to make use of the product, and finally, for elements that cannot return to the environment due to their properties, it is necessary to bet on recycling. In short, the main premise of circular economy is that waste becomes a resource (Macarthur, 2013; Files, 2015).

Price, in 1963, defined science as that which is published in scientific journals and the scientist as the person who has collaborated by writing in one of those journals (Furner, 2003). As scientific research becomes increasingly global, interdisciplinary, and collaborative, it is necessary to understand the state of art of a given discipline starting with a bibliometric study, which offers a worldwide view of the state of art and the study of its evolution allows for the analysis of changing trends in that particular scientific field (Kurtz and Bollen, 2012).

The bibliometric study and the use of its indicators are essential scientific instruments because they provide an accurate quantification of knowledge in a given scientific field and its compilation in bibliographical databases. Bibliometric studies undoubtedly facilitate the understanding of research activities in a specific scientific field, regardless of the objections that can and should be made. However, it must be noted that, in general, bibliometric analyses are valid in those areas in which scientific literature is an essential result of research. The aim of this article will therefore be to provide an overview of scientific publications in the field of recycling, with a special focus on the category of materials.

Data

The coexistence of two large scientific databases, Scopus and WoS, raises the question of the stability of the statistics obtained by one or the other sources of information. Several studies have measured the overlap between databases and the impact of using

Fig. 1 Trend over time.

different data sources for specific research fields on bibliometric indicators, demonstrating a larger number of journals indexed by Scopus compared with WoS (Mongeon and Paul-Hus, 2016); regarding the overlap, 84% of the WoS titles are also indexed in Scopus, while only 54% of the Scopus titles are indexed in WoS (Gavel and Iselid, 2008). For example, some studies related to citations in the papers conclude that each database covered 90% of the citations in the other database when the citation period is limited to Scopus citation coverage, from 1996 onward (Bosman *et al.*, 2006). The use of the Scopus database for bibliometric studies is fully extended in different fields such as education (Diem and Wolter, 2013), energy (Manzano-Agugliaro *et al.*, 2013), medicine (Garrido-Cardenas *et al.*, 2018a,b), or environment (Brimblecombe and Grossi, 2009).

One of the world's largest databases of scientific literature is Elsevier's Scopus, which contains approximately 18,000 titles from more than 5000 international publishers, including coverage of 16,500 peer-reviewed journals in the areas of science, technology, medicine, and social sciences, including the arts and humanities. For this reason, Scopus was selected for this work.

The Scopus database has been consulted with the following search string: TITLE-ABS-KEY ("recycling") AND (LIMIT-TO (SUBJAREA, "MATE")), of which more than 28,000 results have been obtained in the period between 1969 and 2018.

Results

Trend Over Time and Types of Publications

Fig. 1 shows the evolution in time of the recycling works published in the category of materials. It is observed that since the recycling symbol was designed in 1970, and the United States celebrated the first Earth Day, the trend has been upward, but especially since 1990, reaching a local maximum point in 2010, where the trend of growth has been constant, reaching more than 2000 publications a year from 2017.

With regard to the type of publication (Fig. 2), it can be seen that 74% are articles, while 17% are conference papers. When the research topic is very novel, the percentage of conference paper is higher than the percentage of articles, and when it is a consolidated topic the percentage of books is more representative, around 10%. This indicates that the subject of recycling in the category of materials is a topic of growing research, but that it is not yet fully mature, as the percentage of books is still quite low.

Subjects From Worldwide Publications

The categories in which the research is distributed are relevant because it can be seen which areas are working on the issue of recycling materials. Fig. 3 shows the distribution by subject category to which the Scopus database has assigned them. It can be seen that it is dominated by the engineering category with 34%, followed by three other categories of similar size, around 15%: chemistry, physics and astronomy, and chemical engineering. These first four categories account for about 80% of the scientific production of recycling in matters of materials. If we add to this the categories of energy and environmental sciences, it reaches 90%. Then, there are a whole series of categories, which we could qualify as minor because they are about 1%, showing the

Fig. 2 Distribution of publications type.

Fig. 3 Distribution of subject category.

importance of the subject as it is addressed from many points of view: Business, management and accounting; earth and planetary sciences; biochemistry, genetics and molecular biology; computer science; mathematics; agricultural and biological sciences; economics, econometrics and finance; medicine; immunology and microbiology; arts and humanities; and others.

Journals and Proceedings Metric Analysis

One of the most important elements of a bibliometric study is the publication media in which the works object of the study is published. This offers a relative importance of the field under study, compared with other similar studies. The assessment of scientific journals with bibliometric indicators has been largely driven by the impact factor since the 1970s. The journal impact factor is defined as all citations to the journal in the current JCR year to items published in the previous two years, divided by the total number of scholarly items (these comprise articles, reviews, and proceedings papers) published in the journal in the previous two years. On the other hand, Elsevier has decided to include in Scopus among other indicators the CiteScore. CiteScore metrics are part of the Scopus basket of journal metrics that includes SNIP, SJR, citation and document

Table 1 Main journals and their metrics

Journal/meeting	%	N	Impact factor (2017)	Citescore	Highest percentile/category	TH index	Citations (C)	C/N
Construction and Building Materials	3.83	1072	3.485	4.22	96% civil and structural engineering	74	11,604	10.82
Journal of Nuclear Materials	2.46	688	2.447	2.51	86% nuclear energy and engineering	48	7827	11.38
Journal of Applied Polymer Science	2.39	669	1.901	1.87	73% polymers and plastics	46	7879	11.78
Desalination	1.93	539	6.603	6.41	98% water science and technology	61	12,224	22.68
TMS Annual Meeting	1.41	394	–	0.12	14% metals and alloys	11	607	1.54
Materials Science Forum	1.29	362	–	0.3	22% general materials science	13	908	2.51
Key Engineering Materials	1.27	356	–	0.29	21% general materials science	10	610	1.71
Iop Conference Series Materials, Science and Engineering	1.09	305	–	0.49	42% 157/270 general engineering	12	221	0.72
Journal of Materials in Civil Engineering	1.03	289	1.763	1.94	81% building and construction	44	5022	17.38
Polymer Degradation and Stability	1.02	285	3.193	3.59	91% mechanics of materials	52	5830	20.46

counts, and percentage cited. The integration of these metrics into Scopus provides insights into the citation impact of more than 22,220 titles. CiteScore is the number of citations received by a journal in one year to documents published in the three previous years, divided by the number of documents indexed in Scopus published in those same three years. The two main strengths of this index are as follows:

- (1) Three years is the best choice for a wide-ranging database, as it includes a representative proportion of citations from all disciplines, while reflecting relatively recent data. Especially if compared with the two years of the impact factor (IF) or the five years of impact factor (5-year journal Impact Factor), both of the JCR (Journal Citation Reports).
- (2) All document types are included in both the numerator and denominator, making it difficult to manipulate the calculation of this indicator.

Table 1 shows the main media where recycling topics are published in the category of materials. The top 10 sources by number of publications have been taken into account. The relative percentage of publications has been calculated for the search terms, observing a great dispersion, since it by no means reaches 5% of the total of the publications. The leading journal in this ranking is *Construction and Building Materials* with 3.83%, followed by *Journal of Nuclear Materials* with 2.46%, and, in third place, *Journal of Applied Polymer Science* with 2.39%. It can be seen that journals rank very well in their specific categories, all of them being in the first quartile, that is, above 75% of the category in which they are indexed. These categories are civil and structural engineering, nuclear energy and engineering, polymers and plastics, water science and technology, building and construction, and mechanics of materials. It is also remarkable that journals do not repeat any category, although apparently the titles of the journals may seem the opposite. However, in the meetings some appear in the same category (general materials science).

Another indicator that has been calculated in this section is the TH-index. The H-index is used as an indicator of a certain author or journal, and is calculated by counting the number of publications for which an author has been cited by other authors at least that same number of times. So, the TH-index is calculated by counting the number of publications for which journal manuscripts have been cited by other manuscripts at least that same number of times. This ranking of TH-index is led by the journals *Construction and Building Materials* (74), *Desalination* (61), and *Polymer Degradation and Stability* (52).

Finally, the average citations of the articles published in the subject (C/N) of recycling in the category of materials have been calculated. This ranking is no longer necessarily led by the journals that publish more on the subject such as *Desalination* (22.68), but is followed by others such as *Polymer Degradation and Stability* (20.46), and *Journal of Materials in Civil Engineering* (17.38), which are not the most productive in this field.

Countries, Affiliations, and Their Main Topics

The main countries that publish materials on recycling are shown in **Fig. 4**. It can be seen that this ranking is led by countries with more than 3000 publications, including the United States and China, followed by Japan with more than 2000. With more than 1000 publications are, in fourth place, Germany, fifth, United Kingdom, and sixth, India. And with more than 800 publications highlighted in order of importance: South Korea, France, Spain, Italy, and Brazil. In general it is observed in **Fig. 5** that the great areas of the world that do not investigate in this field are the African countries, Central America, and the central zone of Asia. Perhaps this can be attributed to less industrialized geographical areas.

If this analysis is made taking into account the institutions (**Fig. 5**), it is observed that this ranking is led by Chinese institutions, with three of them among the top five, specifically the first place occupied by the Ministry of Education China, second place Chinese Academy of Sciences, and fifth place University of Science and Technology Beijing. It can also be observed how among this

Fig. 4 Worldwide distribution of the publications.

Fig. 5 Main institutions.

top 5 are two Japanese institutions: In third and fourth place, with the University of Tokyo and the Tohoku University. It is noteworthy, given the ranking of countries, that the first institution in the United States, Oak Ridge National Laboratory, is ranked 11th in the ranking of institutions, with no more in the top 20. This suggests that the United States, despite being a world leader in this field, does not have any institution strongly focused on this field, and this research is spread among the set of research institutions in this country.

The first German institution, the Rheinisch-Westfälische Technische Hochschule Aachen, occupy the 8th place in this ranking of institutions, and the Forschungszentrum Jülich FZJ, the 13th place, the latter being one of the largest interdisciplinary research centers in Europe. The first UK institution, The Royal Institute of Technology KTH, ranks 27th. For South Korea, Korea Institute of Geoscience and Mineral Resources in position 20; for France, CNRS Centre National de la Recherche Scientifique in position 6; for Spain, Universitat Politècnica de Catalunya in position 21; for Italy, Consiglio Nazionale delle Ricerche in position 31 and Brazil, Universidade de São Paulo (USP) in position 7.

Table 2 Main keywords

Keyword	N	%
Mechanical properties	2076	2.72
Concretes	1341	1.75
Scanning electron microscopy	1296	1.69
Tensile strength	1212	1.58
Aggregates	1166	1.52
Water recycling	1164	1.52
Compressive strength	1112	1.45
Concrete aggregates	1065	1.39
Fibers	979	1.28
Polymers	944	1.23
Environmental impact	851	1.11
Aluminum	820	1.07
Scrap metal reprocessing	811	1.06
Slags	784	1.02
Sustainable development	760	0.99
Environmental protection	730	0.95
Polypropylenes	729	0.95
Polyethylene terephthalates	718	0.94
Degradation	697	0.91
Composite materials	690	0.90
Wastewater treatment	687	0.90
X-ray diffraction	678	0.88
Catalysis	661	0.86

Keywords From Worldwide Publications

Keywords are ideas and topics that define the research content. In addition, keywords are blocks of text that help search engines identify the topics of the research. If the keywords of all the articles studied are analyzed, and with them a cloud of words is made (Fig. 6), one can have a visual idea of the content of the global research. Of course, search terms, *recycling* and *materials*, appear in it at a larger size, but it also highlights everything that is important: Water, plastic, metals, paper, waste, aluminum, etc. Apart from a quantitative idea of the topic, a table has been elaborated with the frequency that these keywords appear in the analyzed works (Table 2). Thus it is observed that *mechanical properties* is the keyword that dominates although below are other very related as *tensile strength* or *compressive strength*. The concretes appear in an outstanding second place, but they also have quite a few variants such as *concrete aggregates* or *aggregates*.

Water recycling, as expected, also appears very prominently, although there are quite number of variants within the keywords used: *Wastewater*, *wastewater reclamation*, *wastewater treatment*, *water*, *water absorption*, or *water treatment*. Fibers play a leading role in the recycling of materials such as glass fibers (Zhou and Qiu, 2010; Zheng *et al.*, 2009) and carbon-fiber (Schinner *et al.*, 1996; Liu *et al.*, 2004; Morin *et al.*, 2012).

With regard to the techniques used, scanning electron microscopy is observed as very outstanding and to a lesser extent X-ray diffraction, thermogravimetric analysis, transmission electron microscopy, and chemical analysis.

Polymers are other materials frequently studied, and although there are many types of synthetic polymers such as nylon, Bakelite, or polyethylene, it is the latter that has an important role in the subject of recycling, as it is one of the most common plastics due to its low price, and simplicity in its manufacture. Within the highlighted keywords are *polypropylenes* or *polyethylene terephthalates*. The PPs are recycled as thermoplastic elastomers (Ismail and Suryadiansyah, 2002). On the other hand, quite a few lines of research propose to use the polyethylene terephthalates as an additive to concrete, given its mechanical properties (Jo *et al.*, 2006; Choi *et al.*, 2009).

Clusters Analysis Based on Keywords

If the relationship between the articles cited among them referring to the subject of recycling in the category of materials is represented, Fig. 7 is obtained. Ten clusters have been obtained, of which the first eight are representative because they have more than 1% of the publications.

Table 3 shows the first 5 keywords of each cluster, which has allowed its classification. The largest cluster is for plastics with 35% of publications, followed by the concrete cluster with just over 18% of publications. In third place is the rubbers cluster with almost 12%. It is followed in fourth and fifth place by the aluminum and blast furnace clusters, with more than 9% each. In sixth and seventh place are the batteries (7.7%) and paper (4.2%) clusters. The last significant cluster is wastewater, with 3.5%.

Regarding the grouping within the general subject of recycling (Fig. 7), it is observed how the two most compact clusters are plastics and concrete. The rubbers cluster is quite close to both but is very integrated with the plastics, as expected. The other clusters are more dispersed, but the wastewater theme draws attention, which is clearly isolated from the rest and seems to be linked only to the plastics theme. The blast furnace, although it dominates the topic of the recycling of gases, is close to the rubbers. It is also remarkable how far away is the recycling of paper from water, because as it will be seen they have quite a lot in common, unless it is a specific recycling of water for this type of industry.

The critical public debate on natural resource conservation and recycling has led to a renewed interest in biomaterials, leading to research into renewable raw materials (Mohanty *et al.*, 2000). The elimination of traditional composite material structures, generally made of glass, carbon reinforced with epoxy, unsaturated polyester, or phenolics, is considered essential for global sustainability. So, in the first cluster, is found the recycling of polymers or waste products based on low-density polyethylene, HDPE, or PP using chemical recycling methods such as pyrolysis or dissolution/precipitation (Achilias *et al.*, 2007). In this type

Fig. 7 Community detection of worldwide research on material recycling: Clusters.

Table 3 Cluster analysis

Cluster	%	Name	Keyword				
			1	2	3	4	5
7	34.95	Plastics	Mechanical properties	Composites	Degradation	Polypropylene	Chemical recycling
5	18.61	Concrete	Recycled aggregate	Durability	Concrete	Mechanical properties	Rice husk ash
8	11.83	Rubbers	Mechanical properties	Devulcanization	Rubber	Polyurethane	Glycolysis
1	9.87	Aluminum	Aluminum	Life cycle assessment	Accumulation	Impurity	Magnesium
0	9.14	Blast furnace	Blast furnace	Coke	Oxygen blast furnace	Top gas recycling	Zinc
9	7.7	Batteries	Leaching	Hydrometallurgy	Cobalt	Permanent magnets	Silicon
4	4.23	Paper	Deinking	Flotation	Reclaimed fibers	Paper recycling	Pulp properties
3	3.46	Wastewater	Reverse osmosis	Nanofiltration	Membrane bioreactor	Water reuse	Photocatalysis

of work there is an enormous amount of research dealing with the study of mechanical properties (Arbelaz et al., 2005) such as rigidity (Bourmaud and Baley, 2009), but also rheology or calorimetric properties (Bourmaud and Baley, 2007).

The second cluster is focused on concrete. Most of the world's total production of solid waste comes from construction and demolition waste (Rao et al., 2007). Construction waste materials typically go to landfill, where concrete waste accounts for approximately 50% of it (Tam, 2008). One of the most widespread methods of recycling concrete waste is the generation of recycled aggregates (Tabsh and Abdelfatah, 2009). What is striking about this study is the frequent occurrence of the term RHA. However, it is something that has been studied for a long time, above all as a replacement for cement to make concrete, especially as a binder material (Bui et al., 2005; Givi et al., 2010). For example, RHA has a positive effect on the concrete compressive strength at early ages (Rodríguez De Sensale, 2006).

The third cluster is focused on rubber. An average car tire can travel about 30,000 km over its lifetime before it needs to be replaced. So, nearly 1 billion rubber tires are thrown away each year. If they are not recycled, they end up in landfills. As an example, in Sulabiya (Kuwait) is the world's biggest tire graveyard. Since 2006 EU rules have banned the disposal of tires in landfill sites. Rubber residues are among the most difficult materials to recycle as they do not dissolve or melt. The recycling of rubber can be achieved by size reduction and production of powders (Fang et al., 2002), devulcanization (Green, 2007), reclaiming (Gaustad et al., 2012) and recovery of chemicals (Shinzato and Hypolito, 2005) and energy (Rabah, 2003).

The fourth cluster is focused on aluminum recycling. Aluminum is the most abundant metal in the Earth's crust, accounting for approximately 8% of the weight of the Earth's solid surface (International Aluminum Institute, 2009). The highest concentration of aluminum oxide is found in bauxite ore, but despite being very abundant it is also one of the most expensive metals to obtain. Pure aluminum is obtained by extracting alumina from bauxite. The great cost of this process is the energy required for its production, as each ton of aluminum requires more than 15 MWh of energy, which means a cost of 25%–40% of the final price of aluminum and hence aluminum is one of the most expensive metals to obtain. In fact, Iceland is becoming one of the largest producers of aluminum, and that which has no bauxite ore, but what it does is "sell" its energy from its geothermal power stations and five large hydroelectric reservoirs that collect water from glaciers, using part of this energy in the transformation of bauxite into aluminum, as this energy cannot be stored. Note that energy in Iceland is 30% cheaper than in the United States. This same circumstance is happening with the United Arab Emirates in the production of aluminum. The most widely accepted industrial method for producing alumina from bauxite is based on the dissolution of bauxite with soda, then by different decanting, separation, and calcination processes; thus alumina (Al_2O_3) is obtained. Alumina is electrolyzed by the Hall–Héroult process to finally obtain aluminum. Thus, 1.9 kg of alumina produces 1 kg of pure aluminum.

From an environmental point of view, obtaining aluminum is a highly polluting process, both in the extraction of bauxite, and in the subsequent processes commented on in the conversion of bauxite to aluminum. Thus, its recycling is a major issue, as well as the high cost of this material and the serious environmental consequences. Used aluminum arrives mainly through two channels: Domestic waste (e.g., used beverage cans) and industrial waste (e.g., electricity cables, lithographic sheets, vehicle scrapping, or construction demolition).

The cluster obtained shows that they appear as keywords *accumulation* and *impurity*. This is because the accumulation of impurities in these recycled material streams may provide a significant compositional barrier to the recycling goals (Gaustad et al., 2012). The keyword *magnesium* linked to aluminum recycling is due to aluminum–magnesium alloys (Shinzato and Hypolito, 2005). For example, in 2003 the existing recycling system was updated by introducing the elimination of coating paint and the reduction of magnesium losses during the melting process of used beverage cans (Rabah, 2003). Today, approximately 30% of the aluminum used is provided by recycling plants (International Aluminum Institute, 2009).

Iron and steel alloys remain the key materials in the automotive, construction, marine, and many other industries due to their strength, hardness, versatility, and low cost. The fifth cluster obtained is related to blast furnace and top gas recycling. One of the central functions of the blast furnace is iron making. For example, iron ores with lower iron content such as taconite are first processed to concentrate the iron level and drive off volatile impurities. This process uses coke. A specialized type of coal, called hard coal, is used to make coke, a porous form of carbon. Coke is a reductant, or a chemical, that can reduce iron oxide to iron metal. One of the main goals of this process is minimizing CO_2 emission; this is top gas recycling (Murai et al., 2008). It should be

noted that CO₂ has many uses such as carbonated beverages, protective atmosphere packaging, electronics, oil extraction, chemical industry, inertization metals, pulp and paper, environmental testing, iron and steel industry, welding, food transport, or water treatment. Unlike other gases, air separation is not the main source of carbon dioxide. The cheapest way to produce carbon dioxide is to recover it as a subproduct from the production processes of other factories or from natural wells.

Cluster 6 is about batteries. Battery recycling can be a great opportunity for the development of the world economy and the preservation of the environment. Batteries' main component, lead, is almost 100% recyclable and can be used endlessly in the manufacture of new batteries, without the need for new raw materials and their extraction from natural reserves. In addition, batteries made from recycled material have the same quality and offer the same performance as their equivalents made from new raw materials. In this cluster there are keywords linked to lead research such as leaching or cobalt. Above all, the used lithium-ion batteries have cobalt and lithium as cathodic active materials (Lee and Rhee, 2003). Research is focused on finding environmentally friendly leaching processes (Li *et al.*, 2010).

The advantages of paper recycling are well-known (cluster 7), for example, the amount of forest cut is reduced, the need to plant monocultures of conifers and eucalyptus trees is reduced, water consumption is reduced by 85%, energy consumption is reduced by 65%, polluting effluents are reduced by 35%, or landfill space is reduced. The fact that it is cluster number 7 in terms of the importance of the research carried out does not mean that it is less important, but that it is a well-known process and the associated technology is fully mature, despite which research in this field continues. One of the most studied problems in this field is deinking. As an example, Europe's pulp and paper industry produces 11 million tonnes of waste annually, 70% of which comes from the production of deinked recycled paper (Monte *et al.*, 2009). So, paper machines and bleaching plants generate a huge amount of effluents in this industrial process (Ochoa de Alda, 2008); the World Bank recommended wastewater reduction including the recycling of wastewater with simultaneous recovery of fibers.

Finally, there is the recycling or treatment of water for reuse, cluster 8. In this cluster there are five main lines that are currently being researched in this field: Reverse osmosis, nanofiltration, membrane bioreactor, water reuse, and photocatalysis.

Augmented Reality and Occupational Safety

Dušan Tatić, University of Niš, Niš, Serbia

© 2020 Elsevier Inc. All rights reserved.

Introduction

Placing the worker in a safety-management context is very important due to current practices in the working environment that ensure uninterrupted functioning of the everyday job routine. Exposure to risks, caused by unsecure handling, can lead to hazardous situations that often result in injuries and delays in finishing technological processes. Therefore, safety measures have to be appreciated by strictly following the rules prescribed for each particular task by occupational safety experts. Although protection measures are precisely defined, there is a need to ensure and further improve their application in the industrial environment.

The advent of information technologies, accompanied by new hardware solutions such as smart mobile devices, enables a quick and precise display of safety instructions in the workplace. Consequently, they can be efficiently used in improving occupational safety conditions, especially in the industrial environment.

The emerging augmented reality (AR) technologies, coupled with ubiquitous mobile devices, can be used as an interface between the working environment and the worker, since they enable the presentation of relevant safety information in a distinct and intuitive way at a particular work location. In this way, the worker will be precisely informed about the security measures which need to be implemented prior to performing the concrete task assigned. Therefore, providing virtual safety information combined with a real space image during realization of daily tasks can help in reducing the error rate.

Application of Augmented Reality in Industry

The application of AR in industry is a field of study with rapidly increasing interest (Navab, 2004; Fite-Georgel, 2011; Blanco-Novoa *et al.*, 2018; Jetter *et al.*, 2018). AR as a significant aid during the daily work process is described in (Gimeno *et al.*, 2013; Re *et al.*, 2016; Benbelkacem *et al.*, 2013; Wang *et al.*, 2014b). This kind of research focuses on fields such as maintenance and repair that are a part of various complex industrial systems where the worker gets predefined virtual information during everyday routine work (Zhu *et al.*, 2014; Koch *et al.*, 2014; Henderson and Feiner, 2011; Scurati *et al.*, 2018; Palmarini *et al.*, 2018). Also, there are research papers discussing manufacturing (Yew *et al.*, 2016; Uva *et al.*, 2018) and assembling (Wang *et al.*, 2016) of complex systems by using AR to improve the efficiency of implementing the related procedures. Systems based on AR presented in the relevant literature also address problems in industry fields such as collaboration (Wang *et al.*, 2014a; Zhou *et al.*, 2011), management (Espíndola *et al.*, 2013), and product design (Park and Moon, 2013; Arroyave-Tobón *et al.*, 2015) with the main goal of improving communication between worker groups gathered on the same industrial project.

Training systems are a special field of application of AR (De Crescenzo *et al.*, 2011; Watanuki and Hou, 2010; Borsci *et al.*, 2015; Yim and Seong, 2010), usually represented as virtual guidance. This provides a more complete and easier way to perceive and understand information compared to the usual approaches based on classical printed manuals.

Different types of hardware aids are proposed for resolving particular tasks by using AR technology. By pointing the camera of a mobile device such as a smartphone and tablet towards a predefined spot, while walking in an industrial environment, the worker can get job instructions (Webel *et al.*, 2013; Schall *et al.*, 2013). While scanning the industry space, one or both hands are occupied and the worker has to watch each instruction before he can perform any action. This can be viewed as a drawback of that approach. Therefore, Head Mounted (HMD) or Head Worn Devices (HWD) such as smart glasses and smart helmets are recommended instead of mobile devices (Syberfeldt *et al.*, 2017). By using such a device, assistive information is projected on the glass atop the worker's head during work. Reduced field of view is often considered as a limiting factor in the widespread use of these devices. An alternative could be found in projection systems which combine the image of the real world with computer generated multimedia content on a suitably positioned big screen or directly on the work surface (Fiorentino *et al.*, 2014; Di Donato *et al.*, 2015).

Occupational Safety in Industry and Augmented Reality

An emerging field of potential research in computing concerns the application of augmented reality technology in improving occupational safety. Combination of industrial safety and AR is used to help workers realize tasks with a necessary simultaneous protection against hazards and risks in the industrial workplace (Grabowski *et al.*, 2018; Velosa *et al.*, 2018).

It has been observed by many experts in the area that in industry, workers often neglect security signals and then end up in a risky situation while performing task. On the other hand, traditional methods for issuing security signals are not efficient enough. These methods are often static and tend to interfere with other workers by giving a warning signal to more than just the intended recipient. Augmented reality technology can be used to improve the release of security signals. In (Dzwiarek and Luczak, 2008) the

issuance of security signals was defined through smart glasses in combination with AR technology. It turned out that the warning elements displayed should be as simple and easy to recognize as possible.

The work (Kim *et al.*, 2016b) presents a study in which experts from several different industries have been interviewed to define the current state and future development of the AR HWD system for industry needs. It turned out that only a well-executed combination of AR and HWD systems can contribute both to improving safety and health at work and to the successful execution of work tasks. Also, certain limitations of AR HWD systems are mentioned, as well as recommendations for the development of potential applications through this technology.

The construction industry is a very complex environment in which workers are exposed to risk of injury at work (Li *et al.*, 2018). Most accidents are caused by the human factor; therefore, new methods of protection should be explored. Usually prevention of accidents is done by educating workers, but pedagogical methods of occupational safety are mainly theoretical without much practice in the field. Therefore, a system for improving occupational safety with the help of virtual and augmented reality technologies has been described in Le *et al.* (2015). The system is implemented on mobile devices and consists of a user interface, content editing part and a database. An evaluation of the developed prototype has shown that such a system can significantly improve learning about error identification and application of security procedures. In this system, the time required for the creation of educational scenarios has been pointed out as a disadvantage.

Another study involving the construction industry where augmented reality technology is used for safety improvement is presented in Talmaki *et al.* (2010). Due to the complexity of installations that are located below ground, which require changes, careful excavation in exact places is necessary. This necessitates careful work at these exact locations without much room for mismatches. Augmented reality technology is used to display data from a geospatial database in the form of a 3D model and in this way provide the precise position of the installations during excavation. The simulation of excavations is realized inside an excavator cabin where a monitor displays the data about the installations in the field by using a combination of AR technology and a GPS system.

Natural catastrophes lead to damage of urban areas after which it is necessary to analyze the consequences. In order to evaluate building damage and safety, a system (Kim *et al.*, 2016a) has been proposed to assist security risk assessment. The system is designed to use AR technology on mobile devices to compare the situation before and after the disaster. Based on insight into the current and previous state, an expert for risk assessment is able to quickly determine the degree of damage and the security level for the use of that facility.

Incidents in nuclear installations cause long-term consequences and adversely affect environment. In such situations, human evacuation is a primary goal where modern technology such as AR can be helpful. The integration of the geographic information system and augmented reality technology that facilitates the evacuation of people is presented in Tsai *et al.* (2012). Using this mobile system, shelters can be reached faster, and the evacuation of people performed efficiently. An improvement of this system is shown in Tsai and Yau (2013). Indoor orientation has been introduced, as well as the integration of 3D models that help the evacuation. Two additional mechanisms are also integrated: (1) An alarm which converts text into sound that is activated in the vicinity of the shelter for more accurate guidance, and (2) an SMS service, to help in case of problems during the evacuation. An experimental evaluation shown that the improved system is a better solution.

Occupational Safety Framework for Industry Purposes

AR technologies enable the development of an occupational safety framework tailored for different industrial environments and various circumstances in which hazardous situations can occur. As an example, we will present such a framework derived from an analysis of injuries which occur during the daily work process in an industry environment (Fig. 1). It can be observed that the causes of injuries are either inadequate training in the case of less qualified workers, monotony of the job and excessive self-confidence of high qualified workers due to which they often tend to skip some of safety procedures. Therefore, an augmented reality system is realized with the intention of providing occupational safety (OS) instructions and work and maintenance (WM) instructions during job execution in an industry environment (Tatić and Tešić, 2017). The system in Tatić and Tešić (2017) is realized as a client server application where the client part is realized as a mobile application.

The model of the system is based on an analysis of technological process in a thermal power plant. Each task in the technological process is divided into OS instructions defined by a safety officer and WM instructions issued by a technology officer. The information provided to the worker depends on his qualification level, so that less qualified workers get a detailed set of working and safety instructions, while highly qualified workers get a reduced set of WM instructions. Each worker gets the same set of OS instructions and is required to confirm their implementation.

Determination of the task content is done upon the authorization from the mobile device. Task data such as safety and work instructions are stored in a database and linked to the multimedia content in a Multimedia repository. Communication between the mobile device and database application is realized by the REST service on the server side.

Upon successful registration, data are transferred on the client side by a Communication module that is responsible for communication with the server. Data are stored in the Task module that regulates issuing of current and saved information about the implemented OS and WM instructions. After each occupational safety instruction, the next work and maintenance instruction is projected on the screen of the mobile device.

Fig. 1 Occupational safety framework based on augmented reality.

The user interface module navigates the user to find the exact spot in the concrete work environment and scan it with his mobile device. At the same time, the AR module responsible for visualization of OS and WM instructions is activated. Upon scanning, elements of the User interface module are removed from the screen and the AR instructions are shown during the tracking.

The worker is obliged to watch and perform the given instructions. A single instruction is active at a time and only one location can be tracked. When the worker stops tracking, the checking system is projected. The worker must pass verification that the current instruction is finished in order to get the next instruction. A double check procedure is realized to prevent unintended confirmation. After confirmation of the current occupational safety instruction, the next working instruction is issued. The data about each finished instruction are stored in the database for further analysis and control of the entire technological processes over an extended period of time.

Conclusion

As can be seen from a literature review, the augmented reality is an attractive research field for industrial applications. Due to the continuous advent of mobile hardware this technology become widely applicable in different areas of industry. Special attention is devoted to the usage of AR in occupational safety where some concrete application have been already shown. We present an occupational safety framework based on augmented reality aimed at preventing risk and injuries by issuing work and occupational safety instructions directly at the workplace.

Barriers and Benefits Towards Sustainability Driven Business Models

Rajagopal, EGADE Business School, Tecnológico de Monterrey, Mexico City, Mexico

© 2020 Elsevier Inc. All rights reserved.

Introduction

Debate on sustainable development in manufacturing and business dates back to mid-twentieth century, which rose into prominence with growing environmental concerns. Over time, the concept of sustainability has been tagged with the various operations of industry, business, and society, which became a part of ethical governance. Sustainability and efficiency in business domain are considered as socio-political ethical parameters to measure the public performance of businesses today. However, the concept of sustainability in business still remains obscure and theoretical as not much efforts have been put in implementing sustainability plans in business through public-private partnership. Generating social awareness and civic consciousness, about eco-friendly responsibilities and consumption patterns under the broad framework of green consumerism, has yet to taken to the heights of industrialization. Though sustainability in business has been achieved to a large extent through social and workplace engagements in developed economies, the benefits of sustainability in business is yet to be realized fully in the emerging markets. Sustainable development in business can achieve its potential by integrating stakeholders into the planning and measurement systems of business enterprises. The terms of reference for sustainability in business need to be made obligatory by the governing authorities and articulated by the business leaders at the level of their organizations.

Innovating sustainable business model is about creating superior customer- and firm value by involving stakeholders and market players such as supply chain and packaging partners. Sustainable business model of a company addresses societal and environmental needs in through integrated business operations. For example, the Finnish oil refiner Neste uses sustainable and renewable raw materials for its fuels, and produces premium quality traffic-fuels that generate 90% less emissions than conventional fuels. Neste provides environmental training across all its sites and ensures that the palm oil it uses is certified by the 'Roundtable on Sustainable Palm Oil'. Sustainability enables business strategy to grow in the company in general and as an integral part of its corporate responsibility plans in particular. In industrial products manufacturing companies alike Neste, safety management and practices, and increasing the use of waste and residues in the production of renewable products are administered as topical strategic focus areas. These areas require sharing of competence and cooperation across inter- and intra-organizational infrastructures (Bocken *et al.*, 2019).

Business models in manufacturing companies require a purposive design to deliver desired sustainability impacts in the society and industry. 'Ecosystems' of different business models are specific to the purpose and the corporate goals of the companies. Some companies that grow with social innovation objectives have a greater number of qualitative designs encompassing social needs, stakeholder education, user value generation, and bridging the corporate social responsibilities. Social sustainability manifests itself in corporate culture, organizational behavior, and functional practices of companies. Some aspects of socially sustainable culture demonstrated by European companies can be well correlated with their corporate reputation and financial success. The success-driven social sustainability dimensions of corporate culture include sustainability strategy and leadership, mission, communication and learning, social care and work life, and loyalty and identification. In addition to other indicators related to measure the business performance of a company, the above mentioned indicators are taken into consideration for a company to be classified as financially successful. Thus, companies and stakeholders intending to manage social sustainability proactively need to undertake participatory projects with key partners and stakeholders on cultural change and development initiatives towards sustainability (Schönborn *et al.*, 2019).

In order to create and measure the impact of sustainable business models on environment, society, economy and other key stakeholders; collaborative and longitudinal approaches over phased project timeline work better. Hence, a systemic form of sustainable business model can be developed to ensure clarity in propositions and constructs, and make geo-demographic expansion possible. Sustainable business models are spread longitudinally, so they are bound to face unforeseen risks which need to be managed in association with the stakeholders. However, companies must engage in mapping the performance of pilot business-experimentation models. Such performance maps of business sustainability models help companies combine economic, environmental and social components of sustainability, and integrate the concept of social and stakeholder thresholds into the logic composite index of corporate sustainability. Benefits could be associated with the concepts of carrying capacity, safe minimum standards and critical capital (Nikolaou *et al.*, 2019).

This article discusses the process of designing and management of sustainability-driven business models in manufacturing and services companies. It contributes to research on sustainable innovation, design, and experimentation of business model. It argues the need for understanding ecosystems of different business models and integrating them on social and cultural foundations of the society. It also guides managers how to develop business model innovations to achieve the sustainability performance.

Literature Review

Companies have become social assets than just profit-making business bodies today. Companies increasingly emphasize on corporate social responsibility, governance on sustainability, and public-private participation for business-society wellbeing to

cater to social and environmental needs. Exploring strategic orientations towards the interface between business and society in order to influence organizations' sustainability performance has become a major challenge in the twenty-first century, as global community have gone critical on wider business-society nexus (Nijhof *et al.*, 2019). Business plans related to corporate sustainability have built a social sentiment across industries, which encourages companies to solve ecological, social, and economic problems. Such efforts require more resources, greater commitment, and higher stakeholder participation towards developing new products, new processes, or new organizational designs (Hahn *et al.*, 2017). The need of the hour is to develop robust strategic orientations with right stewardship to link business with society, and to draw an impact of business model innovations on sustainability performance and dynamic managerial capability.

Most manufacturing companies are revising their business models in accordance with the shifts in societal-, stakeholder-, and regulatory requirements. Business model innovation has emerged as a key advantage for companies to augment financial- and sustainability performance. Emerging companies acquire capability to move into new business models rapidly and successfully by exploring involvement of stakeholders in creating mutual values. Cognitive dimensions (knowledge, emotions, and self-image congruence) and corporate resources (budgetary allocations, collaborative business models, stakeholders) are important determinants to achieve sustainable competitive advantage for companies (Geissdoerfer *et al.*, 2018). However, using new technologies in sustainability programs is often difficult for companies, as there remains a wide gap between the diffusion and adaptation of technology under various social and cultural conditions. Technological advances towards sustainability are incremental and many companies find it difficult to meet their sustainability targets. Innovation in business models help to align social and stakeholder benefits, and revenue stream management to leverage sustainable solutions (Rashid *et al.*, 2013).

Business model innovations tend to yield higher returns than product or process innovations (Lindgardt *et al.*, 2009), while sustainable business models might deliver value added community benefits. Such business models not only add societal and stakeholder values, but also help in exploring business diversification with sustainable growth. Bio-mimicry companies aiming at industrial and community products have gained high growth and performance over time and expanded geo-demographically with several co-creation opportunities. Bio-mimicry driven business models in construction industries have helped companies to grow sustainable. The construction industry has significant and adverse impacts on the environment such as pollution, high-energy consumptions, amongst others (Oguntona and Aigbavboa, 2017).

Successful businesses in manufacturing and service sectors tend to understand the challenges and opportunities linked to business transition towards sustainability in a society today. They disseminate awareness in the society on sustainable products and services on environment and green consumption perspectives. Companies are able to innovate sustainability-linked business design in context of their focus on corporate social responsibility and build business models that are functional in this context (Franca *et al.*, 2017). For example, Nestlé links its business models with the sustainability projects on improving environmental performance focusing on water conservation, reducing food loss and waste, organic cultivation of coffee and food grains, and managing climate change effects at local levels. Large companies develop a strategic sustainability framework within the business model canvas. However, during this process, the business case of sustainability is often not understood profoundly by the companies as the scope of vision and system of business planning are inadequately managed. Business model innovations in a company thus aim at achieving sustainability impact on society and stakeholders by improving the organizational competence to bring people together into systematic public-private ventures. However, such corporate efforts are slow and complex (Birkie, 2018).

Companies with focus on sustainability-linked business development plans can be successful in the long term by creating value for both stakeholders and society through a holistic approach. This approach is defined as Creating Shared Value (CSV), which serves as the fundamental guiding principle for consumer-centric companies. Through CSV, sustainable development can be easily integrated into business activities. Such business models with sustainability focus is increasingly attracting long-term investors and involving unrelenting stakeholder participation. CSV brings business and society together by generating values for the local livelihood economy, global economic concerns, and value for society. Sustainability-linked business model innovations span beyond ecological and environmental protection perspectives, and cater to foods and nutrition, health, and social wellness dimensions. These extended objectives of sustainability-linked business model innovations serve as value added solutions towards creating a better civilization on the planet by improving the quality of life and human participation. Under such business models, partnerships between government, people, and companies are formed to create shared value, which functions as institutional frameworks for the development of sustainable agricultural production, rural non-farm industries, renewable energy, water, and silviculture (Senevirathna, 2018). Rural development programs for farmers offer commercial differentiation to consumers in developing countries. These programs are the responsible stewardships on managing sustainable natural resources like land fertility and water conservation; and help in reducing production costs and securing supplies for agri-business companies.

Successful business model innovation embedding objectives of sustainability attract global investors, funding from international organizations, and political and technological support for effective implementation of sustainability projects. Long-term investors can ensure companies to employ adequate capital and human resources for carrying out corporate social responsibility (CSR) projects, which maximizes stakeholder value. These investors increase the value to stakeholders of CSR activities not through higher cash flow, but through lower cash-flow risk with effective implementation of the sustainability projects. CSR engagements of companies, with local impact on communities and stakeholders, are the key performance indicators used to measure the sustainability projects. The wider social impact on stakeholders, quality-of-life index, and environment protection objectives is the main driver that explains higher stakeholder value and operating performance of business model innovations with focus on sustainability (Byun and Oh, 2018).

In sustainability-driven business model innovations, transport ecosystems are more critical than other services domains as the transport systems contribute to the greater environmental degradations than natural resources. Carbon emissions, partial pollution, and air quality deterioration are widely caused by the unregulated transport services. In order to reduce the transportation-related environmental degradation and to improve sustainability in the transport services industry, the shared 'logistics business-model innovation' has geared-up global concerns. This new economic model has been supported by technology that gives companies, people, and other players in transport services industry an opportunity to share and monetize the excess capacity of their assets comprising vehicles, houses, parking spaces, *etc.* It is an innovative initiative aimed at wider effects on sustainability. However, potential effects of this model are difficult to quantify, but it has been ventured that this new economic relationship would yield greater efficiency to businesses across the world, especially in the supply chain and city logistics processes. Application of the shared economy model to logistics brings up concepts of logistics sharing capacity. Logistics sharing capacity assumes the access and sharing of operational capabilities, either by pooling transportation services, by vehicle capacity sharing, sharing warehousing or infrastructure sharing, and leads to improved environmental sustainability in the region (Melo *et al.*, 2019).

The transformative business sustainability (TBS) model has emerged as an innovative model of stakeholders and sources in sustainable business practices, which helps companies in building an interface with stakeholders, and exchanging plans of resource residuals. TBS model of sustainable development complements and emphasizes the importance of commitment to far-reaching goals through corporate leadership in critically manifested areas of strategic priority such as energy, water, soil conservation, air quality control, organic farming, and managing non-biodegradable waste. Such transformation business models purposively respond to current and future environmental regulation and social needs involving stakeholders and all market players. In recent developments, efforts aimed towards business sustainability and application of sustainable business practices have expanded beyond corporate initiatives, which involve interfaces and interactions between stakeholders, market players, and sources (Wagner and Svensson, 2014).

Although business models of any type, whether innovative or transformative, deliver desired impact on sustainability; few tools that assist in sustainable business modeling need to be categorically identified by the companies to measure their impact on society, stakeholders, key partners, and targeted resources (land, water, energy, environment *etc.*). New businesses intending to create sustainability-linked business models focus on balanced social, environmental and economic value. A value-mapping tool thus need to be developed for each sustainability project to help companies create value propositions. A multifaceted value-measuring tool supports sustainable business modeling on three forms of value (captured value; disguised value either missed, destroyed or wasted; and opportunity) and four major stakeholder groups including environment, society, customer, and network players (Bocken *et al.*, 2013).

Business model innovation for sustainability, therefore, can be defined as innovation that creates significant impacts for the environment and society through changes planned by an organization to create value-network among stakeholders, market players, and companies. Business model archetypes embed one or more sustainable development projects as goals of the company for creating and delivering social values. Minimum viable archetype models for sustainability focus on value proposition in products- or services-deliveries designed to provide maximum possible usable life, and on providing environmental and social sustainability. Most consumer-centric companies are offering consumer education on the use of the sustainable products and services to add long-term economic gains (Birkie, 2018).

Business Model Innovation

Business model innovation (BMI) with focus on sustainability is beyond simple discovery of new mode of value proposition, value capture and value creation, as the process involves stakeholders to explore social and environmental needs in association with the companies. Business-to-consumer companies give priority to resolve environmental effects of their products and services on the society for innovating their business models. BMI allows the entrepreneurial firms operating at local level, also to reconfigure the value creation mechanisms and increase the performance (Desyllas and Sako, 2013).

Cognitive process of business model on sustainability is widely influenced by social and economic needs. The business model for recycling of polyethylene terephthalate bottles has different social and geo-demographic dimensions. Ecologically minded constructors in developing countries have decided to try to address the issue of low-cost and atmospherically-controlled housing by repurposing plastic bottles as a construction material. Plastic bottles have been used to build not only houses, but also water wells, raised bed gardens, and garden sheds. Beverage manufacturing companies have also come-up with similar theme to address in their social sustainability projects (Twumasi and Oppong, 2017). In a socio-commercial innovation, 'pickup and drop' business model for sharing services within the circular economy, developed by automobile rental companies, became iconic as it meets the sustainability concerns in developed countries like the USA. Business models for sustainability have been proved to increase economic performance, and collaborative product recovery management in many African countries. These models are used to develop business strategies for people and companies with long-term socio-commercial objectives to sustain in the market. Sustainable business development models integrate three bottom line concepts: protecting environment, and improving economic and social performance (Ray and Mondal, 2017).

Business model innovation with focus on sustainability has the philosophy of giving more for fewer returns, unlike investing in business for profit. It is a featured concept of effective altruism adapted by companies to grow in the society. Corporate social responsibility has a latent sense of altruism, which is exhibited more apparently in the community than other socio-economic

services projects. Altruistic trend in companies show pro-social goals regardless of whether reputational incentives or returns on social investment are present (Simpson and Willer, 2008). Reciprocity is an underlying driver of social sustainability, which tends to bridge the gap between business and society. The principles of reciprocity build social sustainability by increasing trust and cooperation among people in the society, and stakeholders and employees of the company. From a difference perspective, organizational and societal social sustainability are mutually reinforcing in the long-run, and they stay discrete over time and space. Such connectivity between the sustainability concerns of society and business explains a complex relationship (Roca-Puig, 2019). However, quick reciprocity in sustainability based business models is a far cry.

Business model innovation embedding sustainability projects broadly moves through four stages: conceptualization, determining key indicators, drafting business model innovation, and sustainable consumption. The canvas of business model innovation is exhibited in Fig. 1, which illustrates that corporate goals for working on sustainability projects should be profoundly connected with the society and stakeholders. Sustainability projects are commonly long-term projects and need longitudinal evaluations. Therefore, adequate allocation of resources (capital, human resources, and technology) is one of the critical requirements in business model innovations. Though businesses are increasingly adopting sustainability, the environment continues to decline. One the most critical reasons of failure of sustainability projects is their inability to integrate micro and macro perspectives of sustainability. Corporate sustainability and environmental management can be determined as macro factors, while corporate social responsibility and sustainability development are micro aspects, as they are need based and involve community. Thus, corporate social responsibility and sustainability development should be addressed together by companies over and above a simple business case (Landrum, 2018).

Companies need to explore opportunities for sustainable social development and value perceptions in order to connect stakeholders and business models. Sustainable social development has widespread issues, and its outreach has both latitudinal (geo-demographic or spatial) and longitudinal (over time or temporal) effects (Hervani et al., 2017). Sustainable social development is a blend of social and environmental goals. Therefore, pursuing social goals is generally associated with higher environmental impacts; though interactions differ across geo-demographic segments and depend on specific target-oriented goals. Although efforts by high- and low-income groups are needed in developing and implementing sustainable social development projects, companies need to reinforce the social needs and encourage participation also by involving non-governmental organizations. Given the importance of both social and environmental sustainability, the sustainable development goals laid by United Nations need to be clearly understood by companies to develop business model innovations (Scherer et al., 2018).

There are several ways to link sustainable social development with the corporate business models, as shown in Fig. 1. It ranges from environmental conservation projects to reduce the depletion of natural resources. Consumer centric companies are engaged in sustainable agriculture, developing green by-products emerging from ecological conservation projects. In developing countries, sericulture (silk farming using silkworms), worm farming (role of earthworms in soil fertility and soil structure), and apiculture (beekeeping and extraction of honey and natural paraffin) have risen into prominence as an outgrowth of silviculture and sustainable farming projects. Stakeholders contribute significantly in developing sustainability projects with the companies, and in carrying out the implementation of projects at the field level. Accordingly, stakeholders collaborate, co-create, and co-manage

Fig. 1 Business models with focus on sustainability. Source: Author.

sustainability projects. Value perceptions of sustainability projects integrated into business model innovations are closely associated with the development needs, economic growth, and quality-of-life improvement of society in general and stakeholders of the company in particular. Sustainable social development projects have spanned over long time and their measurable impact is longitudinal.

The key indicators in developing business model innovation with focus on sustainability are largely profit- and market oriented. Companies grow with profit-making concerns, and cannot ever serve as non-governmental organizations or non-profit institutions. Companies look for return on investment made in sustainable social development projects sooner or later. Therefore, integrating sustainable social development projects into business model(s) is the only option for the companies. As the sustainability projects are embedded in the business models of companies, all elements on the business-modeling canvas need to be considered. Among the elements of canvas, measuring cost-time-risk (CTR factors), key partners, possible shared resources, predetermined revenue stream and its management, social value generation, investment on social-innovation, and analyzing market trends make significant contributions.

Business model innovation should clearly explain the implementation process of sustainability projects by clear project identification; developing a comprehensive project charter involving the stakeholders; and stage-gate process map demonstrating the spread of stages in the project and list of quality checks as gate for each stage in the project lifetime. Most companies invest in technology to drive sustainability projects. This task has two major challenges of technology diffusion and stakeholder education. Commonly, there exists a wide gap between technology diffusion and creating technology awareness, which causes low response among stakeholders on adapting to new technology. Technologies can be improved in a dyadic manner, both as 'learning-by-doing', and adapting the technology to local conditions. However, advanced technology has potentially greater returns on capital investment, and to 'learning-by-doing' to stimulate stakeholders for its adaptation (Lahiri *et al.*, 2018). Sustainability projects often deliver delayed outcome as the gestation period of such projects are prolonged. However, companies invest time and resources to achieve sustainable effects. For example, landscape designing in public places or common properties is a labor-intensive sustainability approach to landscape management. Projects must ensure to impart systemic knowledge on the sustainability benefits, and drive collaborative action between stakeholders and project owners (company). Collaborative design projects facilitate implementation of complex sustainability projects like community landscaping and biofuels management (Lucia *et al.*, 2018).

Marketing Sustainability Projects

Sustainability is a social concept, and sustainable products like green energy, organic products, and environmental services are social products. Linking sustainability to business models poses major challenge to companies on marketing of such social products, as they are off-stream, trigger voluntary consumption, and need to be backed thorough consumer education. Therefore, sustainability is broadly tagged with social marketing perspectives and challenges. Sustainability business models invariably incorporate marketing plans, which is referred as social, green, and critical sustainable marketing. Social sustainable marketing follows the logic of demand-driven marketing management and undertakes the responsibility for sustainable development outside the firm. Green sustainable marketing projects are initially oriented towards consumer education and develop proactive marketing strategies within existing institutional structures in the long run. Such marketing strategy guides sustainable development in the firm. Critical sustainable marketing aims for reassessment of assumptions of the existing market systems, which prevents social sustainability and green consumption behavior. Companies can achieve success in marketing of sustainable products and services by carrying out extensive sustainable development in society and industry (van Dam, 2017).

A new commercial reality in today's global marketplace is the rapid shift in consumer behavior due to the emergence of dynamic disruption of innovation and technology in consumer products on a previously unimagined scale of magnitude. Environmental sustainability and consumption of green products has driven the world towards converging openness, transparency, and commonality. However, most consumer-centric companies have shifted their strategy emphasis from sustainability to customization by reorienting marketing strategies on hedonic, functional, reliable, and utilitarian values; and low prices. They benefit from enormous economies of scale in production, distribution, marketing, and management. The growing concept of circular economy has given further boost to companies to adapt to the public-private policies of marketing sustainability driven products. Combining sustainable consumption with the circular economy concept could reduce the incidence of resource scarcity and climate change by reducing resource use and increasing cycling of products. To achieve sustainable consumption in a circular economy, production and consumption practices need to shift to sustainable measures. Business models can potentially influence both practices as they define how a company conducts business and shapes the company-consumer relationship (Tunn *et al.*, 2019).

Corporate consciousness on marketing of sustainable products has emerged in the early decade of twenty-first century by generating awareness among consumers. Such efforts have made a major impact on transforming the regional markets in setting vogue, cultural values, and social validity for multidimensional growth of companies. However, growing trends in consumption of eco-friendly, green, and organic products, due to social media effects and experiential marketing, have appeared to be strong catalytic elements in drifting consumer behavior. Growth of sustainability projects converging business-to-business, business-to-consumers, and consumer-to-consumer business models has been the most successful design of ecofriendly companies such as IKEA, Unilever, Panasonic, and IBM. However, some firms in a niche have also evolved organizational designs that signal a new way of resolving challenges within the sustainability-linked business models. For example, a South Korean organic food products company uncovers three consumption practices, which include investing in prolonged wellbeing, expressing sustainability values,

and building self-esteem and social status among consumers. A critical examination of consumer behavior on sustainable products reveals that they are close to modern luxury fashion consumption (Chung *et al.*, 2016).

Opportunities for sustainability-linked businesses through global to local markets are expanding due to the increasing consumer awareness, which is introducing radical shifts in consumption pattern and value perceptions of environmentally sustainable products. The fast-growing markets for sustainable products today have expanded from food portfolios to natural pharmaceutical products, and organic cosmetics to organic clothing due to changing perceived value, sustainability commitment, uniqueness, acquisition from known sources, and lifestyle changes. Ecolabel criteria mainly focus on ecological considerations in production. The connection between ecolabels and clothing designers is expanding rapidly in the developed economies. Many companies look to ecolabelling schemes as the means to set performance criteria and to demonstrate progress to customers (Clancy *et al.*, 2015).

Marketing of environmentally sustainable product suffers from INVUCA, which constitutes investment risks, new products and services management, market vulnerability, behavioral uncertainties of consumers, decision complexities, and ambiguity in marketing strategies. Conventionally, companies have adapted to sustainability-linked business models with a mindset of exploring opportunities to sell their products and services in the global markets. Such companies make cold calls on environmental issues; though they raise public or government funds for sustainable social development projects. However, most companies build their businesses by harnessing the best markets and consumer segments across geo-demographic territories with sharp external focus. Fig. 2 illustrates the cognitive map of consumer perceptions and factors determining consumption pattern for sustainable products.

Fig. 2 explains that companies need to understand consumers and markets simultaneously before setting sustainable products for launch. Cognitive determinants comprise perceptual values and social interface, which act as pull and push factors respectively for consumers to develop consumption preferences for sustainable products over time. Consumers derive perceptual values through 4As, which include awareness about sustainable products, availability within the proximity of consumers, affordability in the context of price and total cost to customers, and scope of adaptability of green products. In addition, perceived use value of consumes, based on perceived benefits, determines the cognitive pull factors. Corporate social responsibility projects implemented by food products companies, to educate consumers on the effect of sustainable and organic products on health and family wellness, have significantly increased consumer demand for these products. The social interfaces in reference to creating peer influence and community awareness, driven by effective corporate-social leadership and motivation, serve as push factors to develop consumption behavior towards sustainable products. Preferences of sustainable products sets a consumption pattern affected by the cognitive influence, linear process of knowledge, attitude and behavior, experience sharing by disseminating user generated contents, and self-image congruence.

Sustainable consumption pattern needed to support marketing strategies can be developed as an outgrowth of social innovation, involving non-governmental organizations in consumer education and production process. Companies intending to develop 'design to sustainability' business model can effectively create consumption eco-systems in the society. The consumption eco-systems guide companies to reinforce their business models in the existing and new markets through high corporate thrust and semiotics to enhance consumer outreach for sustainable products. Such backward linkage would help in building green supply-chain, retaining, and consumption options. In order to make this process effective, governments propose economic policies on sustainable consumption and eco-label certifications, help in creating consumer trust on sustainable products, and reinforce consumer preference towards their consumption. Following the above discussed process, companies can develop markets for sustainable products, and integrate marketing strategy into the business model innovation charter.

Fig. 2 Factors determining consumption pattern for sustainable products. Source: Author.

Rapidly growing technology-based companies harness the resources and ideas by crowdsourcing and analyzing industry attractiveness to achieve a large global footprint quickly. Moreover, operational complexity in the contemporary business environment is about the trade-offs between the social costs and corporate benefits. Therefore, managers need to find the optimal global footprint for their organization (Kerr, 2016). Customer, the end user, is the ultimate target for sustainable social products towards building aggressive and defensive strategies in business. The competing firms try to attract customers by various means to polarize business, and earn confidence in the market place. It is necessary for successful business companies to look for a place of business, which provides them more location advantage, and holds the customers for their goods and services. Business cordoning, or securing trade boundaries, is an essential decision to be taken for building competitive strategies to attack rivals across regions. Even a small business company can compete globally with firms of all sizes through the internet. In managing sustainable products marketing, the institutional and political patronage provides long-term support to the companies. Winning in product, channel and factor market place, in many instances, may not last long in building relationships with the customers. Many business firms have found themselves outmaneuvered in various functional aspects of business by the adept actions of rivals in the institutional arena (Rajagopal, 2016).

Social values are built on cultural dimensions and ethnicity. Egalitarianism and embeddedness of consumers in the society affect the business environment. Thus, companies develop social welfare policies as corporate social responsibilities, and build consumer values. Moreover, social values affect that individual ideological orientation on consumer attitudes towards industry, government policies, and consumer behavior (Arikan and Bloom, 2014). Technology shows significant positive impact on economic growth, while both human capital and technology are important determinants of growth in developing countries and emerging markets. Therefore, improvement of the educational sector, and more funding for research and development among developing countries are prominent considerations to monitor and measure business growth. Such conditions encourage innovations needed to facilitate sustained economic growth (Adelakun, 2011).

Companies invest enormous resources in consumer education to develop brand knowledge, product perceptions, and purchase intentions, using effective advertising, communications, and informal learning on the social media and community platforms. Consumer today buy solutions, not products *per se*. Therefore, consumer centric companies employ resources on consumer research periodically to understand and refresh the consumer needs and preferences. Accordingly, companies offer marketing solutions to consumer with competitive advantage to encourage acquisition and retention of profitable customers. A company in a competitive marketplace manages customers individually, demonstrating how its products or services help in solving problems of buyers and develop higher perceived value. Brand awareness, quality referrals, and sharing of brand experience reap enormous benefits in developing individual relationships with customers. To achieve these goals, companies must become aware of the different types of benefits they offer and convey their value to the appropriate executives in the customer company. Loyal customers display behaviors in a predictable manner, from growing the relationship and providing word-of-mouth endorsements to help company in acquiring new customers (Narayandas, 2005). Consumer behavior is governed by the following synchronized linear cognitive-materialistic-utilitarian relationship among other attributes:

- Knowledge, perception, attitude, and behavior
- Awareness, attributes, affordability, and adaptability
- Validity, value, venue, and vogue
- Engagement, explorative, emotions, and consumption experience

Most consumer centric companies tend to develop positive relationships with consumers to create sustainable buying behavior and perceived values. Consumer centric companies motivate consumers to use new products, perceive their use value, analyze value for money, develop consumption experience, and change their behavior. However, consumers often fail to develop sustainable consumption behavior as companies over-promise and under-deliver product values in the competitive marketplace. In addition, consumers irrationally conceive the product attractiveness, and overestimate their benefits, which causes dissatisfaction and withdrawal behavior of consumers. This leads to a serious behavioral dichotomy among consumers. However, companies can overcome this disconnect by mapping the easy sells, probable failures, complex growth, and co-created consumption experiences. Marketing strategies under each product category has a different ratio of product improvement and consumer value metrics. As companies realize an appropriate fit of products into this strategy grid, they can manage to streamline the consumer behavior, and reduce behavioral inconsistency among consumers. Accordingly, companies can encourage consumers to experiment new products, make improvements in the products to converge product-value with self-congruity of consumers, and reduce the impact of substitute products in the marketplace. Companies can also make their products compatible with substitutable goods by developing brand loyalty, and generating effective psychodynamics among consumer communities (Gourville, 2006).

Consumers commonly tend to generate comprehensive awareness on innovative attributes of products by measuring technology, product life cycle, and their complementarity with other products and services. Most consumers also realign their buying behavior in reference to their self-learned concepts developed out of their previous consumption experience. Consumers update knowledge about the attributes of competitive products. As a result, they learn about value additions, competitive benefits, price and promotions, and serviceability of products to develop purchase intentions. Buying decisions are largely affected by affordability of products in view of consumers' purchasing power. However, most consumer products companies and retailers attract consumers by offering credit support to enhance their purchasing power. Consumer cooperative stores, and delivery of products through public distribution system also augment the purchasing power of consumers. Consumer awareness about brands, analysis

of brand attributes, and their purchasing power required to buy them develop need-based or referred motivations. Such motivations help consumers in adapting to the brands. The quality of referrals, peer experience, and shared decisions also motivate consumers to use sustainable products and adapt them to the social value and lifestyle.

Summing-Up

Sustainable development is a multidisciplinary concept, which combines various fields of knowledge and action including economics, social justice, environmental science and management, business management, politics and global-local laws. It is a debatable domain to argue in real life and real time dimensions on what is required in the society, who are accountable to support the society, and how can the society-industry balance be maintained. Sustainability today has become an outgrowth of social innovation to deliver quality products and services towards sustainable consumption, environment protection, optimization of natural resources, and improving quality of life. As innovation is a key driver for sustainability; the industry players, social representatives, stakeholders, and government agencies are actively involved in diffusing innovation and technology in the society. Therefore, sustainable development is a persistent concern between the society and industry that requires people's action and stringent regulatory requirements from governments. Working on sustainable social development is a continuous process, and project trajectories are the paths, which fortify the development process through learning the behaving of stakeholders and society. It is a crucial element for holistically implementing the sustainable development through local-global innovations. This approach leads to exploring reverse innovation opportunities in social sustainable development (Silvestre and Țircă, 2019).

Society and governments have also looked to business corporations to support social sustainable development, as corporations have more resources than the other entities. Thus, they have always stood as engines for economic and social development. However, companies need to be more proactive in balancing their drive with social equity and environmental protection, though the corporate social responsibility and social sustainability projects discretely contribute to their profit. Besides sustainable production in the agricultural and industrial sectors, achieving sustainable development goals depends also on bolstering the performance of service sector, and improving access to specific services in developing countries. The level of economic development; openness to services trade, and social investment is positively related to financial, information communication technology, and transport services. Appropriate convergence of the macro development factor with micro indicators (stakeholder behavior) in services sector also contributes in achieving the sustainable development goals. Reducing the restrictiveness of services trade policies can enhance performance of the service sector, as openness in services marketing is positively correlated with indicators of sustainable development goals (Fiorini and Hoekman, 2018). However, sustainability concept in business has received mixed reactions due to the latent barriers and benefit that often raise questions on continued investment on sustainable social development. The common barriers and benefits in carrying out sustainability projects are exhibited in Table 1.

Sustainable development as a concept of societal development encompasses some problems that need to be addressed carefully. It can be viewed from the Table 1, that common barriers to implementing sustainability projects are conflict of interest,

Table 1 Barriers and benefits in implementing of sustainability projects

Process	Accountability	Barriers	Benefits
State planned projects	Partially of companies and government	● Project charter and administration ● Resource flow and performance audit ● Transparency in decisions ● Stakeholder engagement	● Long span of projects ● Corporate involvement ● Understanding social dimensions and stakeholder perceptions
Company owned projects	Social-cultural teams within company	● Large volume of financial and human resources ● Non-profitability and longitudinal projects ● Monitoring of sustainability projects	● Creating stakeholder value ● Compliance with government rules ● Tax benefits ● Building corporate image in society
Co-created projects	Public-private partnership	● Lack of clarity of goals ● Public commitment and task management ● Social conflicts and litigations ● Local politics and interventions ● Difficult in monitoring and evaluation of projects due to conflict of interest	● Low pressure on business operations ● Democratic decisions ● Use of voluntary manpower ● Public interest in social development
International alliance projects	Triangular accountability-government, international agency, and company	● Convergence of goals from international to local development concerns ● Operational difficulties due to local laws ● Financial controls and capital workflow ● Commitment, bureaucratic interventions, and goal realization ● Socio-political ideological disruptions	● Availability of funds ● Predetermined goals and project charter ● Clarity of tasks and operations ● Systematic monitoring and evaluation ● Rewards and recognition

commitment, political intervention, and bureaucratization, irrespective of the ownership of the project (government, companies, public, or international agencies). However, there are prolonged benefits from sustainability project to society, but business companies always feel the pinch of high investment for marginal benefits in the long term. The barriers in sustainable development categorically relate to political, financial, and technological limitations. Besides, social and individual lifestyle patterns reduce environmental impact, sustainability concerns, and green economy benefits. Social accountability of sustainability project is one of the major challenges to governments and business houses. It can be stated that implementing sustainability projects is no longer based on goodwill of individuals, but has emerged as responsibility of the entire generation (Mikulcic *et al.*, 2019).

Contribution of sustainable development to corporate sustainability is bi-dimensional. Firstly, it helps leave the areas that companies should focus on: environmental, social, and economic performance towards their commitment to the society at large; and secondly, it provides a business-blended societal goal to work with ecological, social, and economic sustainability projects. However, sustainable development by itself does not provide necessary arguments for why companies should care about these issues. Those arguments come from corporate social responsibility and stakeholder theory. Over the years, there has been intense debate on when stakeholder pressures are effective in driving firms to contribute to sustainable development. Reviewing the institutional theory and slack resources theory, it may be stated that country-level sustainability performance interacts with low- or idle resources in shaping corporate responsiveness to stakeholder pressures (Xiao *et al.*, 2018).

Social institutions play significant role in nurturing cultural heritage which is reflected in individual behavior. Such institutions include family, education, and political structures; and the media affect the ways in which people relate to one another, organize their activities to live in harmony with one another, teach acceptable behavior to succeeding generations, and govern themselves. The status of gender in society, family, social classes, group behavior, and age groups; and how societies define decency and civility; are interpreted differently within every culture. Social institutions are the systems of regulatory norms and rules in pursuit of predetermined goals within the ultimate common value system of a community. An international marketer should evaluate the psychographic and demographic profiles of consumers that indicate the target market of urban and ethnic groups. The firm may choose to provide the marketing communication to the target segments close to their lifestyle (Rajagopal and Zlatev, 2017).

Technological changes are the main impetus behind exploring new opportunities for sustainability and social development advancements. The extent of such change may be explained from hybrid technologies to the appropriate and intermediate technologies. Strategic choices have wide-ranging ripple effects in the organization that determine the key success factors and growth performance or otherwise. Some companies make right strategic choices by improving the implementation process of sustainability projects and reaping long-term advantages. These companies are guided by shared strategic vision, and are driven by responsive attitude towards the sustainability requirements. They emphasize the continuous strive to satisfy the stakeholders. A strategic vision in sustainability may be understood as the guiding theme that explains the nature of business and the future social relations with the industry and governments in general. Such intentions on taking forward the sustainability projects depend on collective analysis of the environment that determines the need for new developments or diversifications. The vision should be commissioned on a concrete understanding of the business and the ability to foresee the impact of market forces on sustainable social development and growth of business. This vision motivates the organization for collaborative business planning and implementation of sustainability projects. Powerful visions are also the statements of intent that create an obsession with winning the socio-commercial goals of the business organizations.

Introduction

Packaging a science, workmanship and technology used to ensure the item with appropriation, convey nutritional data and present the item to buyer (Ojha, 2015; Meena *et al.*, 2017). Different materials are used for packaging in combination with more than one material in the form of metals, glass, wood, paper or pulp, plastic or composite (Kumar and Gupta, 2012). Most of them are enter in the municipal waste streams at the end of their service life (Gale, 2002). Major segment of packaging in India and around the world, are flexible packaging and laminates that is composed of different synthetic plastic. The wide usage of plastic packaging has caused concerns about environmental problem in the world (Green and Tonjes, 2014).

Plastic packaging materials include (polypropylene), polyester (PET), polyethylene, polystyrene and other petroleum-based polymers. Although, a large part of plastic is recyclable in most of the countries. Technically, consumed plastic packaging waste is rarely recycled due to technical and economic constraints. About 1 million tons of plastic wastes are produced annually in China, but about 20% of it is recycled (He and Nie, 2011). A foremost proportion of used plastic remaining waste which is either deposited mainly in landfills or contributes to litter on our roadsides (Gomez and Michel, 2013). The continuous use of synthetic plastic in the form of wastes is raising the general global concerns and makes a bad impact on the environment. These problems arise due to limitations of satisfactory landfill, burning of packaging waste that leads to generation of toxic air pollution.

Biodegradable polymers are specific type of polymer that breaks down through the action of naturally occurring micro-organisms, such as bacteria and fungi, over a period of time result in natural by products such as gases (CO₂ and N₂), water, biomass and inorganic salts. A few biodegradable materials, for example, starch, cellulose, chitosan and so on are utilized for bundling purposes (Table 1). The new and current pattern is to utilize of various biopolymers, for example, starch-PLA mixes; starch-PCL mixes and so forth which are semi-manufactured in nature (Meena *et al.*, 2017).

Classification of Biodegradable Polymer

Natural Biopolymer

Starch-based plastics

The main source of biodegradable plastics is storage of cereals, legumes and tubers, polysaccharide i.e., starch which is a renewable and widely available raw material. A challenge for the development of starch materials is the brittle nature of blends with high concentrations of starch. Plasticizers like glycerol, other low-molecular weight polyhydroxy compounds, polyether and urea are added in blends to overcoming the brittleness of starch for achieving full biodegradability in blends. Plasticizers having property to lowers the water activity thereby limiting microbial growth. Thermoplastic starch (TPS) can be formed by application of thermal

Table 1 Raw materials for biodegradable packaging material

Raw material	Origin	Advantages	Disadvantages
Chitosan	Chitin derivative	Antimicrobial and antifungal activity Good mechanical properties Low oxygen and CO ₂ permeability	High water sensitivity
Zein	Maize protein	Good film forming properties Good tensile and moisture properties Antimicrobial and antifungal activity Good mechanical properties Low oxygen and CO ₂ permeability	More brittle which can be overcome by using plasticizers
Gluten	Wheat derivative	Low cost Good oxygen barrier Good film forming property	High sensitivity to moisture Brittle
Whey protein isolate	Cheese derivative	Good oxygen and aroma barrier	Moderate moisture barrier

and mechanical energy and addition of plasticizers which is used as substitute for polystyrene (PS). When starch is modified to form films that provide adequate mechanical properties of high percentage elongation, tensile and flexural strength, it works as effective packaging material. Starch is modified through either plasticization blending with other materials, genetic or chemical modification or combinations of different approaches. These starch-based thermoplastic materials such as, polyethylene vinyl alcohol or polyvinyl alcohol, polycaprolactone have found wider industrial applications ranging from extrusion applications, injection moulding, blow moulding, film blowing and foaming (Mensitieri *et al.*, 2011).

Cellulose and derivatives

Cellulose is the most richly occurring natural polymer on earth and is an almost linear polymer of anhydroglucose. Due to its hydrophilic nature, insolubility and crystalline structure, its use is very difficult but is a cheap raw material. To prepare cellulose or cellophane film, cellulose is dissolved in an aggressive, toxic mixture of sodium hydroxide and carbon disulphide ("Xanthation") and then recast into sulphuric acid. The produced cellophane is very hydrophilic and moisture sensitive, but it has good mechanical properties. To improve barrier properties Cellophane is often coated with nitrocellulose wax or PVdC (poly vinylidene chloride) and in such form it is used for packaging of baked goods, processed meat, cheese and candies. Commercially a number of cellulose derivatives are produced, mostly carboxymethyl cellulose, methyl cellulose, ethyl cellulose, hydroxyethyl cellulose, hydroxypropyl cellulose and cellulose acetate. Cellulose acetate is widely used in food packaging (baked goods and fresh produce). These are processed by laminating, injection or extrusion moulding and exhibit good film forming properties.

Proteins

Proteins can be divided into two categories one is proteins from plant origin (e.g., gluten, soy, pea and potato) and another included proteins from animal origin (e.g., casein, whey, collagen and keratin). The major drawback of all protein-based plastics, apart from keratin, is their sensitivity towards relative humidity. Blending or lamination with other biobased materials may overcome this challenge with lower sensitivity towards humidity.

- *Casein*

Casein is a milk-derived protein. It is easily processable due to its random coil structure. Materials can be made with mechanical performance varying from stiff and brittle to flexible and tough performance, upon processing of material with suitable plasticizers at temperatures of 80–100°C. Casein melts are highly stretchable making them suitable for film blowing. In general, casein films have an opaque appearance. Casein materials are not soluble in water but they show approximately 50% weight gain after 24 h of immersion. Casein is used as a thermoset plastic for buttons and for bottle labelling.

- *Keratin*

Keratin is cheapest protein. It can be obtained from extraction of waste streams such as hair, nails and feathers. Because of its structure and a high content of cysteine groups its processing is difficult. Fully biodegradable, water insoluble plastic is obtained after processing.

Synthetic Biodegradable Polymer

Synthetic biodegradable polymers are the synthetic ones with hydrolytically unstable linkage in backbone. This is accomplished by utilization of functional groups (for example esters, amides, anhydrides and ortho-esters). Their application in field of packaging is most suitable. For the most part aliphatic polyesters are the dominants of this category.

Aliphatic polyesters

Aliphatic polyesters are most widely studied class of biodegradable polymers, due to their important diversity and its versatility. Basically two routes i.e., polycondensation and ring opening polymerization guiding to the development of synthetic polyesters. Polycondensation of bifunctional monomers specially yields low molecular weight polymers. Ring opening polymerization is favoured when high molecular weight polymers are needed. Most of the biodegradable polyesters are manufactured by means of ring opening polymerization of six or seven member lactones. The aliphatic polyesters are biodegradable in nature because of their hydrolysable ester bonds and approximately all aliphatic compounds are the high molecular weight biodegradable compounds.

- *Poly (glycolic acid) (PGA)*

PGA is an aliphatic polyester. It is crystalline, with a crystallinity of 45%–55% and consequently isn't dissolvable in most organic solvents. It has a high melting point 220–225°C and a glass change temperature of 35–40°C. It is prepared by ring opening polymerization of a cyclic lactone, glycolide. It has amazing mechanical properties. PGA has significant advantage of degradability through simple hydrolysis of the ester backbone in aqueous environment. The polymer is known to lose its strength in 1–2 months when hydrolysed and losses mass within 6–12 months.

- *Poly (lactic acid) (PLA)*

PLA It is a translucent aliphatic polyester prepared entirely from various natural sources found in great abundance like tapioca, corn, sugar beets wheat and etc. It is prepared by repeating units of lactide. It is a semi-crystalline polymer. The level of crystallinity is around 35%–40%. It is a recyclable thermoplastic as the structure doesn't frame crosslink (Yang, 2014). PLA is degraded by simple hydrolysis of the ester bond and does not require the bonding of compounds to catalyze its hydrolysis (Singh *et al.*, 2011). Different routes are used to obtain PLA. PLA, a thermoplastic polymer having high-quality, high-modulus and a hard polymer whose hardness is like acrylic plastic, is not solvent in water and it is totally degraded under compost conditions. It can be made from annual renewable resources so that the industrial packaging area or bio-compatible/bio-absorbable medical devices can provide articles for use in the market (Rasal *et al.*, 2010; Singh *et al.*, 2011). It is effectively prepared on standard plastics hardware to yield shaped parts, film, or filaments. PLA can accomplish excellent mechanical properties if high molecular weight PLA is used as compare to low or medium molecular weight. PLA polymers are materials that have high potential for packaging applications and generate a lot of interest in the packaging industry for its properties and earth-friendly biodegradability. PLA are resistance to oil-based products, seal ability at lower temperatures, and can act as flavour or odour barriers for foodstuffs. Lactic acid, the monomer of PLA may easily be produced by fermentation of carbohydrate feedstock. Carbohydrate feedstock may be agricultural products such as maize, wheat or alternatively may consist of waste products from agriculture or the food industry, such as molasses, whey, green juice, etc. PLA works as a packaging material it is depend on the ratio between the two optical isomers of the lactic acid monomer. When 100% L-PLA monomers are used it results in very high crystallinity and melting point, whereas 90/10% D/L copolymers result in polymerizable melt above its T_g and thus fulfils the requirements of bulk packaging by facilitating it's processing. The first biobased polymer is PLA and it can be shaped into injection moulded objects, films and coatings (Rasal *et al.*, 2010). PLA replaces high-density polyethylene, low-density polyethylene (LDPE) and polyethylene terephthalate.

- *Poly(lactide-co-glycolide) (PLGA)*

L-lactide and DL-lactide have been utilized for copolymerization with glycolic acid monomers (G). The different proportions of Poly (lactide-co-glycolide) have been commercially prepared. A copolymer with a monomer ratio of

25L: 75G monomer ratios – Amorphous polymer

80L: 20G monomer ratios – semi-crystalline.

- *Polyhydroxyalkanoate (PHA)*

PHA are normal, thermoplastic, aliphatic biogenic polyesters that can be naturally cumulated in microbial societies and they vary in their properties relying upon their chemical composition (homo-or copolyester, contained hydroxyl unsaturated fats).

Properties of PHA:

- Water insoluble and relatively resistant to hydrolytic degradation.
- Poor acid and base resistant but good ultra-violet resistance.
- Soluble in chloroform and other chlorinated hydrocarbons.
- Biocompatible thus suitable for medical applications.
- Sinks in water, facilitating its anaerobic biodegradation in sediments.
- Non-toxic.
- Less 'sticky' than traditional polymers when melted.

PHA is a carbon-neutral and important polymer that are bacterial polymer that could be created from numerous renewable carbon sources by microorganisms usually under unbalanced growth conditions, making it a sustainable and environmental-friendly material. At present, there is no competitive cost compared to fossil products.

Encouraging and intensifying research work on PHA is expected to increase its economic viability in the future. Because of mechanical properties of PHAs, they are suitable for substitutions of petro-chemically obtained plastics (polyethylene, polypropylene and so forth.), however as opposed to these item plastics PHA through natural microbiological mineralization, are totally degradable to carbon dioxide and water.

- *Poly-3-hydroxybutyrate (PHB)*

PHB is aliphatic polyester of D (-)-3-hydroxybutyric acid is one of the biodegradable PHA. In 1925 Lemoigne first discovered hydroxyacid (a linear polyester) in bacteria. It is cumulated in intracellular granules by a wide variety of Gram-positive and Gram negative organisms under condition of neutral supplement limitations other than the carbon source. Mostly microscopic organisms like *Alkaignes eutrophus* is utilized for production in which it act as a storage material. A nature of PHB is a linear, semi crystalline and has relatively high glass transition and melting temperatures, are not good features for packaging applications. That's why PHB is synthesized with various co-polymers such as poly-(3-hydroxyvalerate) (HV) leading to a decrease of the glass transitions and melting temperatures to improve flexibility. Current utilizations of PHB-based polymers or composites include the packaging industry, medicine, pharmacy, agriculture, food industry. The characteristics of biodegradability and biocompatibility enable PHAs to be focused in competitive special market sectors. Both PHB homopolymer and PHBV copolyester have been

getting commercial enthusiasm as a promising possibility for the large scale generation of biodegradable and biocompatible thermoplastics.

Properties of PHB:

- Eco-friendly, biodegradable
- Decompose into water and CO₂ by microorganisms
- They are composed of chain of 14 monomeric units.
- Usually molecular weight varies from 2 to 3 × 10³ kDa.
- A good substitute for synthetic plastic.
- Produced from non-replenishing sources.

This basic human friendly polymer has a place with an huge class of biopolymers by PHA and surely understood for their physico-compound properties as normal polymers. Their properties look like synthetic plastic, although the most attractive property of them is production and degradation which is contradictory to synthetic plastic.

● *Poly (3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV)*

Among PHA class, the main biodegradable microbial polymer studied is a copolymer of hydroxybutyrate and hydroxyvalerate (HV). It can be produced by adding propionic acid to nutrient feedstock supplied to bacteria. Mixed carbon source is also used. PHBV is potential environment-friendly substitute for traditional plastics. Many groups have been reported about the structure, mechanical properties and biodegradability of PHBV as biodegradable plastics (Wang, 2005). PHBV is a highly crystalline polymer with a melting point of 108°C and glass transition temperature to the range from −5 to 20°C. The pure copolymer is also brittle and brittle less than PHB. Elongation at break is lower than 15% and elastic modulus is 1.2 GPa. The properties of copolymer can be modified by changing the hydroxyvalerate unit content:

- Melting point of the copolymer as well as the glass transition temperature and the crystallinity decreases as the hydroxyvalerate unit content increases.
- The impact strength increases and the tensile strength decreases with an increase of the HV units. Some of the properties of the PHBV range span convert polypropylene in to polyethylene. But PHBV properties can also be enhanced by adding normal polymer additives such as natural plasticizers, fillers, colorants, etc.

PHBV's have biodegradability, apparent biocompatibility are obtain from renewable resources and the main keys of their wide applications. Primary application areas in which these features connect with some market needs are:

- (1) Disposable personal hygiene: PHBV can be used as the sole structural material or as part of a degradable composite;
- (2) Packaging: PHBV could be used for films, blow moulded bottles, and as a coating on paper
- (3) Medical: Potential in reconstructive surgery and controlled in release fields due to PHBV's biocompatibility coupled with its slow hydrolytic degradation.

● *Polycaprolactone (PCL)*

PCL is obtained from crude oil and biodegradable thermoplastic polymer which is synthetic biodegradable polyester. It has a good resistance to water, oil, solvent and chlorine. Nature of PCL is hydrophobic, semi crystalline polymer and having a glass transition temperature (T_g) of −60°C. Its melting point between 59 and 64°C, dictated by the crystalline nature of PCL which enables the easy formability at relatively low temperatures. A semi-crystalline straight polymer is acquired from ring opening polymerization of ε-caprolactone in presence of tin relatively cheap cyclic compound. The number normal atomic weight of PCL tests fluctuate from 3000 to 90,000 g/mol and can be evaluated by the molecular weight. PCL crystallinity indirectly relies upon the molecular weight i.e., increment in molecular weight tends to decrease in crystallinity.

PCL is a semi-rigid material has a modulus in the scope of low-thickness polyethylene and high density polyethylene, a low elasticity of 23 MPa and has a high extension to break (more than 700 at room temperature). Several copolymers with lactide or glycolide have been developed to improve the degradation rate. PCL has an extensive variety of utilization zone, for example, packaging, therapeutic embed, and controlled drug delivery system framework, so the crystallization and the morphologic properties of PCL are essential. Crystallization is a important procedure due to the last properties of any polymer can be determined by the super structural and small scale space morphology and by large crystallinity. Added substances can be utilized to control the crystallization properties of PCL. Enzyme and fungi can easily biodegrade PCL. Hence, to improve the properties of the native polymer several co-polymeric systems containing PCL have been investigated due to the rapid degradation rate of PCL. Co-polymers of εcaprolactone with DL lactide have yielded materials having high rate of degradation (Alp et al., 2011).

Natural-Synthetic Polymer Blend

This category mainly consists of blends of aliphatic polyester with starch. Due to various disadvantages starch is unsuitable for many applications. These include brittleness in the absence of suitable plasticizers, hydrophilic nature of starch and poor water resistance, deterioration of mechanical properties upon exposure to environmental conditions like humidity, soft and weak nature of starch in the presence of plasticizers. Most of the synthetic polymers are hydrophobic and thermodynamically immiscible with

hydrophilic starch, thus mixing result in phase incompatibility and poor mechanical properties. Ideally, starch and the second polymer should be covalently bonded through existing functional groups or by introduction of new functional groups. One means to improve the characteristics of starch films is through the preparation of composites or blends with other materials such as fibres, nano clays or biodegradable polymers. Studies on starch/polyester blends have focused on the incorporation of starch in the polyester matrix to reduce production costs and maintain the biodegradability.

Starch and poly(vinyl alcohol) (PVA)

PVA is a synthetic polymer which is non-toxic, flexible, and biodegradable and dissolves in water. PVA shows outstanding mechanical and barrier properties and good biocompatibility with high thermal stability. It is also well-matched with starch. The physical properties of PVA, such as resistance, water solubility, thermal characteristics and gas permeability vary with the degree of crystallinity which is highly dependent on the degree of hydrolysis and average molecular weight of the polymer. PVA can be mixed with starch. A soil bacteria *pseudomonas can* completely degrade PVA but under the presence of plasticizer glycerol degradation of pure PVA is very slow. It is the largest synthetic water-soluble material formed in the world and biodegradable in nature and it is compatible to get easily blend with starch. Thus, starch/PVA blends is the most popular biodegradable polymer but it still lacks in mechanical strength and is hydrophilic in nature. The blend with 70% PVA and 30% starch shows the best mechanical strength. Upon addition of nano-filler the mechanical strength has increased significantly in all the samples. Sample with 70% starch shows maximum increase in strength compared to the unfilled sample (Sadhu, 2014).

Starch and PLA

Starch is rich in plants, for example, maize, wheat, potato, rice, and pea, and in this way it is easy and promptly available. Physical treatment of native starch, i.e., disruption of its granular structure, generates thermoplastic starch (TPS), which unfortunately has poor mechanical properties and are inappropriate for use as a polymer matrix. Therefore, it is predominantly used as cheap filler for biodegradable polymers. On the other hand, PLA (produced from the chemical treatment of native starch and sugar) is naturally biodegradable and compostable. PLA has excellent mechanical properties and can be processed using normal equipment and also makes it a promising bio-friendly replacement for many other petrol-based plastics.

Starch-polycaprolactone (PCL) blend

Aliphatic polyesters commonly have good processivity, thermal stability, excellent mechanical properties, good water resistance, and biodegradable thermoplastic polymers with dimensional stability. For achieving the better quality of the blends the compatibility between the natural polymer and the aluminium polyester should be increased and there has been a considerable progress in this regard. Among all biodegradable polymeric materials that are nowadays commercially available, blends based on destructured starch and hydrophobic synthetic polymers, like aliphatic polyesters, have received increasing industrial attention for using as commodity plastics. PCL is biodegradable synthetic polymer. PCL is usually modified by blending with resins or the type of starch used in the polymer blend significantly contributes to the blend resulting in properties for getting better processing and mechanical properties.

Starch-PHB blend and starch-PHBV blend

It was shown that poly (hydroxaclanateate) can make a mixture with polymers in which contain a proper functional group i.e., capable of hydrogen bonding or donor sensor interaction. The properties of mixing films with different ratios of starch are similar. For all samples the glass transition temperature is obtained which are semi-crystalline. A PHB/starch ratio of 70/30 (% wt/wt) has optimum tensile strength. In this particular case a beneficial cost reduction and improved mechanical properties as compared to pure PBB are occurred.

Biodegradable Versus Conventional Packaging Material

Biodegradable material are those material which can be easily decomposed by natural agents like water, oxygen, sun light, microorganisms, etc. These natural agents facilitate the decomposition by breaking the complex organic forms to simpler units. The decomposed matter ultimately mixes or returns back to the soil and thus the soil is once again nourished with various nutrients and minerals. Food waste like vegetable and fruit peels, dead plants and animals, chicken, egg shells, paper materials, garden waste etc., are comes under biodegradable substance. There are many biodegradable and recyclable packaging material alternatives available. These include:

- *Paper and cardboard* – Paper and cardboard is reusable, recyclable and biodegradable. There are a number of advantages in making of this type of product and its packaging and they are readily available. Many packaging manufacturing companies offer an environmental friendly option which has been created using a high proportion of recycled paper.
- *Corn starch* – Items made from corn starch are biodegradable and are ideal for items which have a limited use such as takeaway food. They are good options for all types of food packaging and also make good packaging 'peanuts' to protect and support items when sent through the post. Corn starch packaging biodegrades and has a limited negative impact on the environment.

- *Bubble wrap* – Bubble wrap is widely used as a packaging material. Environmental friendly alternatives include bubble wrap made from recycled polythene and bubble wrap which is completely degradable.
- *Bio-based foam* – Starch-based foam is used as packaging material because of its biodegradability the low costs and low density. Starch can be processed in different ways to make products containing certain properties similar to petroleum-based plastics. The main technical challenges with starch bio-foam have low elasticity, high hardness and high water absorption. To improve strength and water resistance, researchers have added coating with mineral fillers, wood fibre, resin, or wax to starch materials. Cellulose fibres can be used as additives in starch matrix to increase the strength properties such as tensile strength, stress performance, and toughness. In addition these fibres' or natural latex can produce synergistic effects to further improve the functional properties of bio-foam.

Conventional materials are those materials which cannot be broken down or decomposed by natural agents. These substances composed of plastic materials, metal scraps, aluminium cans and bottles, hazardous chemicals etc. It is reported that these things are practically immune to the natural processes and as a result cannot be fed upon or broken down even after thousands of years. Thus, these waste rather than returning back, contribute to solid waste which is very hazardous for the environment. The ever increasing load of non-biodegradable trash is a growing concern all over the world. That's why several countries are looking for eco-friendly alternatives that can minimize the threat on several land and aquatic life forms.

Biodegradable substances on breaking up are converted into simple organic matter and are thus assimilated in the soil and thus become a part of the carbon cycle of the atmosphere. In contrast, conventional substances are resistant to the environmental factors and never decompose and instead contribute to majority of the solid waste. Biodegradable substances can be decompose within a few days or months, whereas non- biodegradable items can take thousands of years or cannot be broken and as it remains in their original form. The costs of bioplastic polymers are generally still much higher than that of their traditional plastic counterparts (Tharanathan, 2003). Bioplastic polymers are hoping to become more valuable in the form of commodity material when an important mass is achieved.

Biodegradable plastics have easily degradable linkages like anhydride, orthoester, esters. Due to the presence of these linkages the molecular weight of the plastic drops down to 1000's from lakhs as a result of degradation. Microorganisms are capable of assimilating these low molecular weight organic materials whose molecular weight is less than 10,000 (approx) and release CO₂, H₂O, CH₄ as metabolic products on other hand non-biodegradable do not contain easily degradable linkages. Their main groups are hydrocarbon groups, amine groups, ester members with hindering groups to prevent easy degradation. So they stay on land without degrading for years. However, when these plastics degrade to molecular weight range of 1000s they will also be assimilated by biological agents as the case of biodegradable plastics. Biodegradable waste is used to produce energy manure, compost and biogas whereas conventional waste can be separated and recycled but the process is very expensive.

Need of Biodegradable Packaging Material

The different applications of Biodegradable material are listed in Table 2. Use of biodegradable material is necessary because of following reasons:

- Many environmental problems resulting from the uncontrolled disposal of plastic wastes can reduce by using biodegradable plastics. They are mainly suitable to recycling alongside organic wastes, as long as the plastics are 'compostable'.
- Biodegradable plastics are used to substitute conventional plastics that produce environmental problems either during use or at their end-of-life. Typical examples are indecently disposed of shopping bags, which can be harmful for sea life, or when conventional plastics packaging becomes contaminated by food, so making it more difficult to recycle.

Table 2 Current application of biopolymers

Packaging application	Biopolymer packaging material	Company
Potato chips	PLA bags	PepsiCo's Frito-lay
Yoghurt	PLA jars	Stonyfield (Danone)
Bread	Paper bags with PLA window	Delhaize (retailer)
Fresh cut fruits and vegetables	Rigid PLA trays and packs	Asda (retailer)
Coffee and tea	Cardboard cups coated with PLA	KLM
Beverages	PLA cups	Mosburger (Japan)
Fresh salads	PLA bowls	McDonald's
Organic tomatoes	Corn-based packaging	Iper supermarkets (Italy) CoopItalia
Milk chocolates	Cornstarch trays	Cadbury Schwepps
Sweets	Metalized cellulose film	Thomton
Organic pasta	Cellulose-based packaging	Birkel
Kiwi	Bio-based trays wrapped with cellulose film	Wal-Mart
Potato chips	Metalized cellulose film	Boulder Canyon

- Compostable plastic bags are also useful in the separate collection of food wastes from households and businesses. These bags can be fully embedded in composting (i.e., material recycling) processes, without causing any negative effect on the compost produced.
- The use of biodegradable products is not the only solution to landfill problems or to the world's environmental issues. However, it should be looked at as a part of the solution along with measures such as reducing consumption, reusing products and recycling.

Disadvantage of Conventional Plastic

- Every year about 100,000 animals such as dolphins, turtle's whales, penguins are killed due to plastic bags. Plastic bags ingested by many animals instead of food, and therefore die and the ingested plastic bag remains intact even after the death and decomposition of the animal. So, it lies around in the landscape where another victim may ingest.
- Conventional plastic contaminate beaches and oceans garbage has been discarded into the oceans for as long as humans have sailed the seven seas or lived on seashores or near waterways flowing into the sea. Use of plastic has increased drastically as a result a huge quantity of nearly indestructible, lightweight material floating in the oceans and ultimately deposited on beaches worldwide.
- Items made from Styrofoam and non-biodegradable plastic wind up in landfills by the ton every year. These products take centuries to degrade and when they do, they can leave toxic residue behind.
- Some of the constituents of plastic such as benzene are known to cause cancer. Plastic resins themselves are flammable and have contributed considerably to several accidents worldwide.

Biodegradation of Polymers

There is a change in polymer properties – tensile strength, colour, size, etc., – in the effect of one or more environmental factors such as heat, light or chemicals of polymer or polymer based product. These changes are usually unwanted such as it reduces the molecular weight of the polymer for changes in the use of products, cracking and depolymerisations, or more rarely desirable, in biodegradation or deliberately lowering the molecular weight of a polymer for recycling. These changes in properties are often called “aging”. Such changes in a finished product are to be stopped or delayed. However degradation may be useful for recycling/ recycling polymer waste to avoid or decrease the environmental pollution. Degradation can be intentionally induced to assist in determining structure. Polymeric molecules are very large (on molecular scale), and unique and useful properties are primarily the result of their size. Any loss in the length of the chain reduces the tensile strength and is the primary cause of premature cracking. Surgeries are most common in India. Mainly metal plates are reserved as the supporting material but now it is replaced by biodegradable polymer materials.

Biodegradation of polymers involves following steps:

- (1) Attachment of the microorganism to the surface of the polymer.
- (2) Growth of the microorganism, using the polymer as a carbon source.
- (3) Ultimate degradation of the polymer.

Normal soil bacteria and water are generally required which adds to the appeal of microbial reduced plastics. Polymers that are based on naturally grown ingredients (like starch or flex fibre) are susceptible to degradation by microorganisms. In the case of materials where starch is used as an additive for conventional plastic matrix and polymer is attacked by microorganisms when it comes in contact with soil or water. Microbes digest starch and leaving behind a porous, spongelic structure with a high interfacial area and less structural strength. When the starch component is minimal, the polymer matrix starts to degrade with enzymatic attack. Each reaction result occurs in the scission of the molecule which helps in gradually reducing the weight of the matrix until the whole material is digested. Another approach to microbial degradation of biopolymers involves growing of microorganisms for the specific purpose of digesting polymer materials. This is more intensive process that ultimately takes more costs and avoid the use of renewable resources as biopolymer feed stocks. The underlying microorganisms are designed to target and break down petroleum-based plastics. Even though this method decreases the volume of waste it does not aid in the preservation of non-renewable resources. Photodegradable polymer undergoes degradation from the action of sunlight. In many cases, polymers are photo chemically attacked, and break up into small pieces. After this the microbial degradation should be to achieve the actual biodegradation. Polyolefin (a type of petroleum based conventional plastic) polymers are considered to be the most susceptible for photodegradation The proposed approaches for further developing photodegradable biopolymers include incorporating additives that speed up photochemical reactions (e.g., benzophenone), modifying the composition of the polymers to include more UV absorbing groups (e.g., carbonyl), and synthesizing new polymers with light sensitive groups.

An application for biodegradable polymers which experience both microbial and photodegradation is in the utilization of disposable mulches and crop frost covers.

The suitable microorganisms are helpfully found in waste water treatment plants. Procter and Gamble has built up an item like Depart, named Nodax PBHB. Nodax is an antacid absorbable; implying that introduction to a solution with a high pH causes a quick basic breakdown of the material. Biopolymer materials which disintegrate upon exposure to aqueous solutions are advantageous for the disposal and transport of biohazards and medical waste (Kumar *et al.*, 2011).

Successful Examples of Commercial Packaging Products Made of Natural Cellulose Fibres

In recent years, different companies launched several fibre-based to replace traditional plastic packaging. These products not only have excellent functionality, but also maintain the underlying benefits associated with natural fibre which also includes biodegradability. Trayforma boards are used for food packaging from Stora Enso (Storaenso, 2017). They can be modified to different designs suitable for various applications. For example, the Trayforma boards used in making of bowls and plates which are made up of top layer (Kraft pulp), middle layer (Kraft pulp + CTMP), bottom layer (Kraft pulp); customer-designed coating may also be applied. Boards can be used as a basic packaging material for heating in a microwave or conventional oven. Södra has launched a bio-composite (Durapulp®), a mixture of cellulose pulp and the biopolymer polylactic acid (Södra, 2016). The bio-composite is suitable for many industrial applications such as moulding, air-laid, sheet or board, for packing food and consumer goods. VTT is developing fibre foam technology (VTT Technical Research Centre of Finland, 2017). The chief raw materials are wood fibre (virgin or recycled), while nanofibrated cellulose can be used to increase specific properties.

Carlsberg has developed Green Fibre Bottle products that can be used for beer (Didone *et al.*, 2017). Paper bottles are prepared by moulding and free of internal liner, and fully biodegradable. Using different bio-based coatings on paper substrate and 100% bio-based stand-up pouches with oxygen, grease and mineral oil barrier properties which is based on the enzymatic fibrillation of cellulose (HefCell) technology developed by VTT (Eagle, 2017). Recently the food service industries have switched to

Table 3 Several patents for biodegradable packaging

Patent	Description	Publication (Year)	References
A biodegradable bio-compostable bio-digestible plastic	Investigation propose a biodegradable bio-compostable bio-digestible plastic and a process for preparation thereof which improves polymer biodegradability/biocompatibility/biodigestion without the loss of physical strength, structural characteristics and also being recyclable in the main recycling stream should the opportunity arise without affecting the stream.	EP 3,162,841 A1 (2017)	(Ravi, 2017)
Biodegradable plastics, method for production thereof and use thereof	Investigation provide a plastic composition which is biodegradable and which does not discharge contaminants during incineration and to provide a plastic composition which does not leave plastic fragments after degrading.	US 9,637,608 B2 (2017)	(Rosen, 2017)
Biodegradable plastic from non-edible natural polymer	Provide a natural biodegradable polymer and its method of production and disclose a non-edible starch based biodegradable plastic composition.	WO 2017/056102 A1 (2017)	(Bali, 2017)
Biobased rubber modifiers for polymer blends	Described polymer blend compositions of polyvinyl chloride (PVC) or polymethylmethacrylate (PMMA) or polyoxymethylene (POM) with polyhydroxy alkanoates (PHAs) that have improved properties including but not limited to improved processability, impact strength, tear resistance, and toughness.	US 9,475,930 B2 (2016)	(Weinlein and Kann, 2016)
Bioplastics	Investigate biodegradable materials based on flours and polymers eg., starch and their thermomechanical processing.	EP 2,432,830 B1 (2013)	(Tangelder <i>et al.</i> , 2013)
Biodegradable disposable labwares for use in laboratories	Invention provide laboratory disposable Supplies which can be degraded in nature without causing environmental contamination while having superior chemical and physical properties for quality products and good processing characteristics applicable to injection/blow moulding.	US2012/0009103 A1 (2012)	(Liu, 2012)
Biodegradable plastic based on fruit waste powder mixture	Invention focus on biodegradable plastics having enhanced rate of biodegradability due to the presence of powdered fruit waste, such as skin and seeds from rambutan, banana, jackfruit and other tropical fruits.	WO2012/078021 (2012)	(Ismail and Aziah, 2012)
Biodegradable cleaner	A cleaning composition is provided in which each of the components of the composition is biodegradable, eliminating the need for the extensive disposal procedures required when discarding prior art cleaning compositions.	US 7,799,145 B2 (2010)	(Thompson, 2010)

biodegradable products made from vegetable and sugar substances such as sugarcane easily in the soil. Since they are made of naturally occurring materials, these products are easily broken into the soil.

Future Prospective for Biodegradable Packaging Materials

Biodegradable polymers are a piece of the bigger plastics market. In Table 3 different patents regarding biodegradable packaging are listed. Food packaging, dishes and cutlery constitute a major market for the product because these materials can be composted with the food waste without sorting, which is a enormous benefit to the waste management effort and to reducing food waste and packaging disposal in landfills. Increasing legislation and consumer pressure are also encouraging retailers and manufacturers to explore these biodegradable products and materials. In the bio-based biodegradable plastic market, there is approximately 66% of the packaging industry which is more than the others. It is expected that with the highest increase in Europe in 2020, the growth of bio-based plastic is high, followed by the United States, then South America and then Asia. Increasing urbanization and the total consumption of packaged products will increase in the expected dramatic increase of Indian middle class from 50 million to 583 million by 2025. The Indian retail market is the fifth largest retail destination globally and it has been ranked second in the most attractive emerging market for investment. Furthermore this the foreign direct investment in multi-brand retail will fuel the packaging industry in the coming years.

Conclusion

There are an unlimited number of such areas where biodegradable polymer material can be used. Environmental friendly polymers are required in areas of agriculture, automotive, medicine, and packaging. Each industry is able to create its own ideal material because the level of biodegradation may be tailored to specific needs. Biodegradable polymers will play a vital role in the packaging sector in future. Natural cellulose fibre's are bio-based materials that are suitable for packaging applications with good biodegradability and recyclability. Although they should be selected and processed according to the requirement of packaging products, keeping in mind the environmental, social and economic sustainability. When cellulose fibre's are used in starch-based foams, it can provide excellent mechanical, vibration and impact cushioning properties. Biodegradable bio plastics are most reasonable for organic waste treatment through industrial or domestic composting and potentially are subject to further demonstration in the anaerobic digestive system. They should ideally be separated at the household level from other, non-biodegradable materials and collects with organic waste, including food waste. The total quantities of waste sent to landfill are reduced and the composts generated can be used as valuable soil improvers by using these biological treatment methods. Bioplastic polymers have great potential to contribute to material recovery and reduction of landfill and use of renewable resources. Effective infrastructure for strict control of mass public awareness and certification, collection, separation and composting of these materials will be important for achieving these benefits in full.

Circular Economy in the Built Environment: Designing, Deconstructing, and Leasing Reusable Products

Fernanda Cruz Rios and David Grau, Arizona State University, Tempe, AZ, United States

© 2020 Elsevier Inc. All rights reserved.

Introduction

The prevalent linear economy model, in which material components are fabricated, built, demolished, and dumped, is not sustainable due to material resource scarcity, energy consumption, emissions, generation of solid waste, and ever-increasing population growth and demand trends. In contrast, the circular economy (CE) model has emerged as a sustainable and alternative approach in which material components are fabricated, built, disassembled, and reused. The CE model aims at increasing material resource and energy efficiency, minimizing waste, and promoting low-carbon footprint. To achieve these goals, the CE model proposes the design of durable components that can be disassembled and reused multiple times in a closed-loop cycle.

The CE model has been inspired by core disciplines in sustainability science, most notably industrial ecology and cradle-to-cradle design. According to [Korhonen et al. \(2018\)](#), the main CE contributions to the body of knowledge are a shift towards sustainable production and consumption culture, the relevance of material durability, and the intertwine between shared economy and sustainable production. In the literature, a diversity of CE definitions exists. The Ellen MacArthur Foundation (EMF) has defined CE as an economy “that is restorative and regenerative by design and aims to keep products, components, and materials at their highest utility and value at all times, distinguishing between technical and biological cycles” ([EMF, 2015](#)). [Geissdoerfer et al. \(2017\)](#) attempted to conceptualize CE as “a regenerative system in which resource input and waste, emission, and energy leakage are minimized by slowing, closing, and narrowing material and energy loops. Such regenerative system can be achieved through long-lasting design, maintenance, repair, reuse, remanufacturing, refurbishing, and recycling”. Following the analysis of 114 definitions, [Kirchherr et al. \(2017\)](#) added that CE aims at accomplishing sustainable development and is enabled by innovative business models and responsible consumers. Even though applicable to any sector, the potential economic, environmental, and social benefits of the CE model can be maximized when implemented in economic sectors with massive material resource consumption, such as design and construction, an activity that result in the built environment that surrounds us.

Indeed, the construction activity represents a leading industry sector that accounted for 12.4% of the gross world product (GWP) in 2014, with such contribution to the global economy estimated to increase to 15% by 2030 ([Global Construction Perspectives and Oxford Economics, 2015](#)). The construction sector is a significant contributor to material resource and energy consumption, and solid waste generation. Construction includes the design and construction of what is commonly referred as the built environment (i.e., buildings, facilities, infrastructures, etc.) but has failed to devise strategies that prevent the demolition and corresponding generation of solid waste once a building, facility, or infrastructure reaches the end its service life. It has been pointed out that current material resource use rates in construction paired with global population growth and consumption trends will result in the scarcity of certain materials, such as steel and copper, which are prevalent in the built environment. However, steel and copper are highly durable materials, which implies that an opportunity for their reuse exists. It is important to clarify that the CE concept of reuse means the reuse of the product or component as is or through refurbishment or remanufacturing but without recycling. Recycling is the process of converting used or waste products into new products, and often requires the consumption of large amounts of water, energy, and the corresponding generation of greenhouse gas emissions. Thus, recycling does contribute to the conservation of raw materials but results in a higher environmental impact than the reuse or remanufacturing (inclusive of refurbishment) of previously-manufactured products. In addition, recycling can encumber highly inefficient steps. For example, it has been documented the shipping of scraps (i.e., recyclable materials) overseas just because of lower production costs. In such case, transportation generated greenhouse emissions and energy consumption that defeated the purpose of recycling from an environmental perspective. As such, the CE model observes recycling as an alternative only when reuse or remanufacturing are not viable ([Stahel, 2016](#)).

Designing products or components with an aim for them to be dismantled and reused is a core competency in the CE approach ([EMF, 2013](#)). Such a design practice is known as design for disassembly (DfD). In the built environment, DfD is also referred as *design for deconstruction* and enables the future disassembly (or deconstruction) of the built assembly with the ultimate goal to facilitate the reuse of their components or products. Complementarily, product-service systems (PSS) enable the collaborative consumption of products and services and thus represents an innovative relationship between supplier and user: selling function instead of volume. PSS focus on extending the services associated with a product complement the CE model with services such as leasing or sharing of products (as opposed to purchasing), in which the reuse of products is an inherent condition. In such PSS approaches, manufacturers are responsible for the maintenance of products, which enables reverse logistics (or take-back), repair, remanufacturing, and reuse. PSS offers building and facility owners highly efficient and sustainable alternatives to services without the burden of ownership and its high investment costs and corresponding depreciation.

Overall, the global problem of resource scarcity demands thinking beyond incremental changes in the linear economy. It demands a holistic, effective, and radical departure that effectively extends the life of construction components and products over

multiple uses. In response to such challenge, the simultaneous use of CE, DfD, and PSS in the built environment is often regarded as a synergistic combination that promises to promote closed-loop cycles while meeting customer and environmental needs in a cost-effective manner.

Circular Economy in the Built Environment

In their cited publication “Towards Circular Economy”, EMF identified construction and demolition (C&D) as a noteworthy opportunity for the implementation of CE. According to EMF, only between 20% and 30% of the C&D waste is recycled or reused, mostly because of the lack of focus on design for disassembly and reuse, which results in a “significant loss of valuable materials for the system” (EMF, 2013). EMF highlighted the central role of design in a shift towards CE:

“At its core, a circular economy aims to ‘design out’ waste. Waste does not exist—products are designed and optimized for a cycle of disassembly and reuse. These tight component and product cycles define the circular economy and set it apart from disposal and even recycling where large amounts of embedded energy and labor are lost” (EMF, 2013, p. 7)

According to Stahel (2016), designing products for reuse must become the norm, and the prefabrication of components and their modularization can be leveraged for that purpose. In modular design and construction, the building is produced in similar “modules” that are built off-site and put together on-site. The process of assembling prefabricated modules in turn offers an opportunity for designing such modules so they can be easily assembled and disassembled and reused in the future. Stahel (2016) claimed that the lack of education about CE and the corresponding fear of the unknown have also prevented its adoption, such that “as a holistic concept, [CE] collides with the silo structures of academia, companies, and administrations”. Urbinati *et al.* (2017) reviewed ongoing CE efforts in 86 companies from various sectors and locations around the world. Only 5 of those companies operated within the built environment. Within those, the authors found that the adoption of CE currently depends on the owner’s commitment and not so much on other factors such as company size, location, or market sector.

Fig. 1 illustrates key factors that, when combined, are prone to create the ideal conditions to promote the adoption of CE. Examples of top-down initiatives include offering market incentives for salvaged materials, increasing landfill fees to increase waste diversion and reuse, implementing take-back policies such as extended producer responsibility, offering credits for CE initiatives in green building rating systems, implementing tax incentives to reduce carbon emissions, and promoting education efforts. Examples of bottom-up initiatives include enhancing product durability, leveraging complementary strategies (such as DfD, PSS, prefabrication and modularization), increasing design collaboration among project stakeholders (e.g., owner, designer, contractor, trade partners) and between them and supply chain actors with advanced design technologies (e.g., Building Information Modeling [BIM]), leveraging tracking technologies such as radio frequency identification (RFID), and exploring CE initiatives within corporate sustainability efforts. Among those, this article focuses on the bottom-up strategies of DfD, reuse, and PSS.

Fig. 2 illustrates the difference between the linear economy and the CE model in the built environment. The linear economy model begins with the extraction of raw materials (e.g., mining, logging). These materials are then manufactured into products and

Fig. 1 CE implementation factors in the built environment. Reproduced from Cruz Rios, F., 2018. Beyond Recycling: Design for Disassembly, Reuse, and the Circular Economy in the Built Environment (PhD thesis). Tempe, Arizona: Arizona State University. Lieder, M., Rashid, A., 2016. Fig. 2 CE and DfD in the built environment.

components, like a steel beam, glazing, insulation, or engineered wood members. Such products and components are eventually installed by contractors in their final position as informed by designers (represented in Fig. 2 as “conventional design”). Once construction is completed, the building, facility, or infrastructure is ready to be operated and maintained, usually for a few decades, until it is demolished. Then, a small portion of the components is salvaged (before demolition) and recycled, while a majority of the components are simply dumped into landfills.

Conversely, the CE model (represented by green arrows in Fig. 2) proposes the disassembly of the building, facility, or infrastructure components by means of a deconstruction process so that they can be reused. Thus, CE proposes a closed-loop cycle that reduces the need for extraction and manufacturing of raw materials into building products. In the CE model, both construction and deconstruction are informed by DfD so that components are fabricated and assembled while facilitating future renovations and deconstruction. Such a closed-loop cycle reduces the extraction of raw materials, embodied energy, carbon emissions, and material/products costs.

Key DfD principles include to (1) properly document “materials and methods” for deconstruction; (2) design of accessible connections that ease dismantling (e.g., designing with bolted, screwed, or nailed connections as opposed to chemical or welded connections); (3) design for production and assembly techniques that facilitate deconstruction, e.g., prefabrication and/or modularization; (4) sort non-recyclable, non-reusable, and non-disposal items, such as those in mechanical, electrical, and plumbing (MEP) systems; (5) standardize components, assemblies, and dimensions; and (6) design according to labor practices, productivity, and safety regulations (Guy and Ciarimboli, 2007).

Despite the potential benefits of DfD, there are a few more than two dozen buildings that have been designed for disassembly. Perhaps the most notable example is the Bullitt Center, in Seattle, known as the greenest commercial building in the world. The Bullitt Center was designed by Miller Hull architects for the Bullitt Foundation with the goal to create a resilient building that would last 300-year. By using DfD strategies like mechanical joints, durable materials and a façade independent of the building structure, the architects have designed for adaptability against future changes in scope or functionality and natural disasters. Dennis Hayes, the president of the Bullitt Foundation, has explained that in the aftermath of a natural disaster the damaged parts would be easily disassembled and replaced. Despite this notorious example, the implementation of the CE model will remain scarce in the built environment as long as CE-prone strategies such as DfD remain anecdotal.

Challenges to CE Implementation in the Built Environment

The challenges to implementing the CE model can be divided into two major groups: barriers against reusing components and barriers against designing for disassembly. The barriers related to the reuse of components include quality, demand, consumer preferences, and knowledge. First, uncertainty about the quantity and quality of used products and components exists. For example, assume a client who needs twenty doors in like-new condition, but the varying quality and uncertain quantity from unreliable-perceived sellers of salvaged components becomes a disincentive for the client who may opt for the investment in new doors -despite higher costs. As DfD facilitates deconstruction and creates new market opportunities, the development of large storage yards is proposed as a partial solution for a stable supply (Environmental Protection Agency, 2008). Also, the regulation of salvaged materials is observed as a potential positive factor in disclosing product/component quality to the final client. Second, the

low demand for salvaged materials is another major barrier against CE. Components are subject to damage during deconstruction, and damages can likely prevent reuse. Such deconstruction issue could eventually be minimized through appropriate deconstruction planning and training. Third, a negative consumer perception about salvaged components exists. Salvaged components are perceived as being inferior in quality compared to virgin materials and components, both aesthetically and for safety reasons (Environmental Protection Agency, 2008).

Finally, there is a lack of research on components reuse and its environmental impact. Research on environmental impacts has focused on the operational phase of the building's or facility's life-cycle. That is because most of the environmental impacts related to the built environment used to be caused by the energy consumption for lighting and heating, ventilating, and air conditioning. In response to that, highly energy-efficient equipment and technologies were developed. As a result, the energy use during the operational phase is much lower than before. Indeed, the building's energy consumption can be entirely offset by renewable energy systems (the so-called NetZero energy buildings). High-efficient buildings with lower or zero energy consumption imply that the other phases of the building's life cycle (e.g., extraction and manufacturing of raw materials, demolition, disposal of solid waste) have a much larger impact than before, and thus mechanisms to reduce their environmental impacts should be investigated. DfD eventually offers the opportunity to reduce such environmental impacts associated with both resource consumption and solid waste generation.

However, there are several reasons why DfD strategies are scarce in the current design practice, such as: architects have little knowledge about DfD; owners have no liability for the building/facility/infrastructure end-of-life; most green building rating systems do not value DfD; and, planning for deconstruction may stretch the project's initial schedule and budget. In addition, DfD guides and manuals list a set of design principles to be followed, and although some of them are feasible in today's practices (modularization and prefabrication), others involve major changes in the way design and construction stakeholders operate (e.g., providing standard and permanent identification of materials chemistry).

In order to drive such change, the reader wants to understand the two reasons why owners (or clients) engage in sustainable concepts through the design of a building or facility: it either makes financial sense, or the client believes that it is "the right thing to do". The former driver represents the *sophisticated* clients and the latter driver represents the *transformational* clients. Obviously, many owners do not fit in either group and consequently have little or no interest in sustainable design. The designer's role, in turn, is to listen to the client and align the goals with those of the design firm. If the designer is aware of DfD and willing to make the effort to plan for future reuse, he or she will need to engage the client. Sophisticated clients want to understand how DfD will increase their ROI, and transformational clients want to understand why DfD is a better choice for the environment.

That a large majority of designers are not aware of DfD or its basic concepts further complicates its adoption. For example, designers often do not understand the difference between reusing and recycling. Similarly, designers aware of DfD express conflicting views about what DfD means in terms of resiliency. Architects often associate the ability to disassemble a building to temporary construction, such as temporary structures or expo pavilions. Some even regard DfD and resiliency as opposites, that is, they think that a "permanent" building or facility does not lend to disassembly. On the contrary, designers with DfD experience note that disassembly actually *enables* resiliency (Cruz Rios, 2018). Designers express that DfD results in a flexible and mutable design that can adapt to future changes in structure, envelope, roofing, or interiors (e.g., partitions).

Finally, the complex design and construction process becomes another prominent barrier against DfD. Each design and construction effort has a unique combination of requirements, codes and regulations, construction methods, schedule, budget, project team, or contractual clauses, among several other factors. Fitting the innovative CE model results in an increased complexity to an already intricate design and construction process. Such increased complexity further prevents DfD adoption.

Overall, the shift towards CE in the construction industry demands research, resources, education, and time. It requires holistic changes in design, business models, supply chain relationships, and codes and regulations. The PSS approach, however, can contribute to activating the implementation of the CE model in the built environment.

Product-Service Systems (PSS): The Future Driver for CE Adoption?

The challenging adoption of the CE model can benefit from the more certain implementation of innovative PPS approaches. The need to improve resource productivity led to the idea of "dematerialization", that is, the reduction of material flows in production and consumption (Mont, 2002). A dematerialized economy is a service-oriented economy, where the consumer values the utilization of the product rather than the product per se. "Functional economy" is another term for a service-based economy, where the manufacturers focus on the provision and performance of services (Mont, 2002). For example, the consumer buys solar power instead of solar panels. Thus, the provider installs and rents (or leases) solar panels for a customer that benefits from solar power without investing in the purchase of solar panels. The objective of a functional economy is to "create the highest possible use value for the longest possible time while consuming as few material resources and energy as possible" (Mont, 2002).

A PSS has been defined as "a marketable set of products and services capable of jointly fulfilling a user's need" (Goedkoop et al., 1999). PSS has been popular among researchers from the mid-1990s (Tukker, 2015) and is perceived inherent to a functional economy. In theory, PSS are designed to be competitive, satisfy customer's needs, and create less environmental impacts than a product-based business approach. PSS tend to close material loops, reduce consumption, and increase resource productivity (Mont, 2002). It also brings benefits to manufacturers, such as adding value to products and increasing their competitiveness, improving relationships with customers and customer's loyalty (because the manufacturer and customer connect through the

product's and/or service's life-cycle), and giving manufacturers an early advantage by anticipating future take-back legislations (Mont, 2002). In a successful PSS, the extended involvement of the manufacturer throughout the product's and/or service's life-cycle enables not only take-back and reuse but also refurbishment, remanufacturing, and product durability as a result of timely maintenance and repairs.

Michelini *et al.* (2017) investigated whether or not researchers agree that PSS increase resource-efficiency and can support the CE model. The authors found very few efforts that connect PSS with CE but noted that the novelty of the topic in the literature. The authors concluded that "PSS have tangible contributions to CE only when the customer pays for the provision of a service instead of the product's ownership". That way, when the service is over, the producer takes back the product, and either leases it to another customer or uses its components to remanufacture the product for a different service (Michelini *et al.*, 2017).

PSS have the potential to create not only environmental and economic benefits but also socio-ethical ones. For instance, leasing high-quality, technically-advanced products can ease the access to such options among low-income populations by minimizing or eventually eliminating initial costs (Vezzoli *et al.*, 2015). Low-income customers can have access to renewable energy by leasing solar panels instead of buying them. Such PSS approach eliminates the burden of the initial investment and enables a reduced power bill whenever energy savings overcome leasing costs.

Case studies have documented how PSS can be implemented in the built environment, for instance, through the Sustainable Product Development Network (SusProNet) project funded by the European Union (Tukker and Tischner, 2006). SusProNet tested many PSS implementations, including those for the construction sector, like the service of recovering and reselling materials and components from demolition or energy conservation systems in residential homes. In the latter approach, the service provider paid the monthly energy bills of homeowners and supplied energy-saving building products. The authors suggested other construction-related PSS concepts in which the supplier provides a "dry environment" to a house instead of selling a roof. The roof is designed by the supplier, who is responsible for maintenance and take-back services.

Another documented application of PSS is the lease and reuse of building components. For example, technology-intensive or expensive components can be leased to owners (such as a university, commercial building, or multi-family apartment complex). Examples of components suitable to be leased include, among many others, perforated copper panels (often used as exterior cladding protection), curtain walls, interior partitions, equipment (such as heating or cooling units), or modularized roof assemblies.

At the time the PSS concept was created, there were three main uncertainties associated with its implementation: (1) the readiness of companies to adopt PSS, (2) the readiness of customers to accept PSS, and (3) the environmental implications related to PSS (Mont, 2002). However, new technology advances can provide the structure required for PSS to happen, such as the creation of new networks (e.g., research networks, information-sharing networks, and industrial symbiosis networks). Recent technologies and tools such as Radio Frequency Identification (RFID), Internet of Things (IoT), Building Information Modeling (BIM), and big data analytics may have an important role in boosting PSS business models (and consequently CE). For example, Ness *et al.* (2015) proposed using RFID coupled with BIM to enable tracking and reuse of steel structural components through their life-cycle. The authors argued that this approach could create "a platform for the company to provide a 'steel service', retaining ownership of the steel over its lifetime, licensing its use by customers in appropriate locations and circumstances, and providing it as part of a PSS, with some similarities to leasing and renting" (Ness *et al.*, 2015).

Besides emerging technologies, policy actions can accelerate the implementation of PSS in the built environment. Such actions can be indirect (e.g., carbon taxes, extended producer responsibility, eco-labeling) or direct (e.g., green public procurement focused on PSS, incentives, support of PSS pilot projects). Policies and regulations can be local, regional, national, or international, and some of them are already being proposed and implemented in European countries.

Introduction

In the recent years, the term triple bottom line (TBL) has gained increased importance in the business world. As also endorsed at the World Summit on Sustainable Development (WSSD), in 2002, under the aegis of United Nations, this concept broadens the focus of an organization from simply the financial bottom line to also include social and environmental concerns. Accordingly, the triple bottom line performance of an organization is collectively considered an indicator of its corporate social responsibility (CSR), economic value and environmental impacts. It is increasingly being realized that the scope and scale of human generated activities continues to put enormous pressure on the natural environment, society, firms, citizens at large and governments. Thus, all such stakeholders have become immensely concerned about the well-being of society and the environment (Tate *et al.*, 2010).

In such a context, the role of supply chains has assumed renewed interest. A supply chain is defined as comprising of all entities involved in fulfilling a customer order (Chopra and Meindl, 2007). The chain is often visualized as consisting of people, organizations and resources which are involved in movement of goods or service from the supplier to customer. A schematic view of a supply chain is depicted in Fig. 1. As shown in the figure, a typical supply chain comprises of several entities starting from the raw material suppliers to the sub-assembly vendors, to manufacturer, wholesaler, retailer, and eventually, for end consumption by the consumer. If we consider the manufacturer as the focal entity in this supply chain, then we can readily classify the various players in the supply chain into two categories – upstream and downstream players.

Much of the supply chain research in the areas of corporate social responsibility (CSR) and sustainability has been confined to a standalone fashion, with relative less appreciation of the interrelationships amongst varied areas such as environment, diversity, human rights, philanthropy, safety, etc. (Carter and Liane Easton, 2011). This state of affairs is found in practice too, when supply chain managers often initiate and manage projects in a standalone fashion, without a clear, holistic, and more strategic understanding of the organization's overall CSR or sustainability position (Carter, 2005). Going beyond these concerns, it is our assertion in this paper, that to get a more holistic and integrative view of the central concept of CSR, as applicable to supply chains, organizations need to take into consideration CSR related efforts of their upstream and downstream players. Such an integrative or holistic overview of CSR indexes would be beneficial to all supply chain players and various stakeholders of the organization at large.

While there are several measurement indicators of CSR practices, which have been discussed in literature, it is evident that (i) there are no common set of metrics for measuring CSR performance of an organization, and (ii) there is no integrative or holistic overview of CSR indexes which is applicable to an entire supply chain. Yet, past literature provides substantive guidance regarding the beneficial effect that the CSR effort of an organization has on its supply chain partners (Carter and Jennings, 2002). Thus, the prime objective of this paper is to posit, based on the extant literature, a general, holistic and integrative overview of CSR indicators in supply chains. Such a set of indicators would be helpful for future researchers as a reference framework to develop further studies in this area of important concern to supply chain managers and researchers.

The rest of this paper is organized as follows. The next section provides a basic foundation of the concept of CSR in an organization. Section "CSR in Supply Chain" provides a basic understanding of the notion of CSR in supply chains. In Section "CSR Imperatives for Supply Chains", we discuss the CSR imperatives for a supply chain. Section "CSR Indicators" provides a broad overview of CSR

Fig. 1 A schematic view of a supply chain.

indicators in supply chain. The next section provides a select group of case studies in a representative industry sector, namely, the textile sector. We conclude in the last section with implications for researchers, managers, and practitioners.

CSR in Organizations

Bowen (1952) first introduced the concept of CSR and stated that organizations, while implementing strategies, should consider society's values. Later, towards the end of 1970s, CSR was redefined in the context of stakeholder theory. Carroll (1979) defines CSR as social responsibility of business encompassing economic, legal, ethical and discretionary (later termed as philanthropic) responsibilities towards the society. Visser (2011) defines CSR in business as creating shared value in society through economic development, good governance, stakeholder responsiveness and environmental improvement. The four responsibilities as stated in Carroll's definition of CSR have been described through varied approaches.

Economic Dimension

In accordance with the minimalist 'economic' approach, CSR has been defined as meeting shareholders' interests through profit generation (Friedman, 1970). According to 'shared value' approach, CSR refers to meeting both business and community interests (Porter and Kramer, 2006). 'Corporate citizenship' approach aligns CSR to social, economic and environmental needs of the society with no or limited benefit to organization (Waddock, 2008). Economic responsibilities of CSR refer to company discharging economic responsibilities towards the society including sustaining viable business model (Carroll, 2016).

Ethical Dimension

Ethical responsibilities of CSR refer to company behaving as per societal and ethical norms by not only complying with legal norms but also following evolving ethical norms (Garriga and Melé, 2004). In accordance with 'stakeholder theory', CSR refers to sustainability and human rights considering stakeholder's perspective. As per 'triple bottom line' approach, ethical responsibilities refer to maximizing economic, social and environmental contributions of the company (Dahlsrud, 2008; Pesmatzoglou *et al.*, 2014).

Legal Dimension

Legal responsibilities refer to companies abiding by state and national laws and following outlined industry standards (Cramer, 2005; Michell and McManus, 2013). Legislative responsibilities of CSR refer to establishing legal ground-rules under which organizations operate and follow minimum standards of set practices (Carroll, 2016).

Philanthropic Dimension

Philanthropic responsibilities of CSR refer to contributing human, monetary and physical resources to the society (Baden, 2016; Carroll, 2016). Philanthropic activities comprise myriad of activities such as giving monetary and service donations and volunteerism by both management and employees for providing service to the community.

These four responsibilities are embodied into classical model of CSR 'Pyramid of Responsibilities' showcased as non-mutually exclusive obligations of managers (Refer Fig. 2). Though Carroll's Pyramid has become an established CSR concept, it was critiqued as it fails to explain the interactional effect of different responsibilities on one another (Visser, 2006; Geva, 2008) and also because the pyramid model was made in reference to developed countries, thus limiting its usage in developing and underdeveloped economies (Visser, 2006).

Visser (2006) developed a CSR model based on Carroll's pyramid to improve the reliability of the model in developing countries. He rearranged the responsibilities in the Carroll's pyramid model (1999). According to the model, economic responsibility receives utmost priority while philanthropic responsibility receives the second highest priority, followed by legal responsibility and ethical responsibility (Refer Fig. 3).

These models are useful as they bring a broad understanding of the CSR concept and describe the CSR theoretical construct though the scope of various responsibilities in the pyramid model that has evolved over the time.

CSR in Supply Chain

CSR has continuously evolved in practice over the years but its application in supply chain has surfaced in the last two decades. A closely related concept of CSR in supply chain management is sustainability. Elkington (1997) defines sustainability as the concept ensuring that our actions today do not limit the economic, social and environmental options to be transferred to the future generations. For example, Adidas addresses sustainability issues right from supplier

Fig. 3 Drivers for CSR pyramid model for developing countries. *Source:* Adapted from Visser, W., 2006. Revisiting carroll's CSR pyramid: An African perspective. In: Huniche, M., Rahbek, E.P. (Eds.), *Corporate Citizenship in Developing Countries New Partnership Perspectives*. Copenhagen: Copenhagen Business School Press, 29–56.

management to effective product design and environmentally friendly packaging. With vertical integration of manufacturing companies operating nationally to contract-based manufacturing across national borders, CSR concept has broadened from individual company's domain to entire supply chain. Moreover, increased pressure by stakeholders especially on multinational companies to implement CSR practices across the supply chain has made it critical for these companies to be responsible for environment and labor practices of not only their own production facilities, but also of their supply chain partners.

Firms can have a two-pronged approach to implement CSR practices along the supply chain: (a) Complying with the CSR standards, and (b) Capacity building. A firm should comply with the established CSR standards, as well as set standards for stakeholders throughout the supply chain and ensure that the stakeholders comply with these standards through strict monitoring process encompassing audits, physical inspection, etc. Capacity building on the other hand, should aim at enhancing their stakeholders' social and environmental responsibilities by closely working with them, focusing on continuous improvement and conducting random audits (Martela, 2005). For example, Pfizer (Pfizer is a multinational pharmaceutical company with headquarters in New York, US) continuously works with its upstream supply chain players to reduce ingredient costs and, at the same time, maintains the highest quality and safety standards; and reserves the right for random audits and site inspections.

CSR Imperatives for Supply Chains

Socially responsible practices should be implemented throughout the supply chain from procurement of raw materials till delivery of the products to the end consumer. For example, Wells Fargo (Wells Fargo is a multinational bank and financial services company headquartered in the U.S. (see “Relevant Websites section”)) is concerned with the social issues of all the communities in which the organization’s entire supply chain operates. We now discuss CSR imperatives for different stages of supply chain.

Procurement

CSR in procurement can be defined as purchasing in accordance with the CSR principles (Maignan *et al.*, 2002). If a company complies with social and environmental standards in the procurement processes, CSR concept can be spread to the suppliers. For example, Walmart has strict supplier agreement under which it demands EHS (Environmental Health and Safety) standards in supplier’s operations; the right to conduct supplier factory EHS audits without prior information; and the supplier’s adherence to Walmart’s requirements in terms of quality, logistics and customer service. CSR practices in procurement also include purchase of recycled and recyclable materials (Zhu *et al.*, 2007), prioritizing suppliers who invest more in environmentally friendly technologies and materials. Companies can also provide training and development of suppliers on the company policy regarding CSR issues.

Production

CSR in production comprise effective product design considering CSR principles (Sarkis, 2003), environment-friendly production process, reduced disposal, prevention of work accidents, improved working conditions, etc. In addition to this, identifying the reuse of the materials at any stage of product life cycle and using it in production and recycling it for the betterment of the society is also a prevalent CSR practice (Büyükoğkan and Vardaloğlu, 2008). Thus, social responsibility can take place both in forward and reverse supply chain management activities. Reverse supply chain management is defined as set of processes and activities which help retrieve end of life or end of use products from customers, for further reuse, repair or resale (Guide and Van Wassenhove, 2002). Reverse supply chain also includes functions such as transportation, product collection and testing, warehousing, inventory management etc. It not only gives economic advantage to the organization by reduction in production costs, but also gives competitive advantage by portraying green image of the organization in the society.

Packaging

CSR in packaging includes use of non-hazardous materials in packaging to protect products. It also includes use of recycled material and consumption of less energy and low waste production in the process (James *et al.*, 2005). Small packaging size and innovative package design for better resource usage is also an important CSR practice in packaging.

Logistics and Transportation

The concept of CSR in logistics and transportation emerged during 1990s and includes giving opportunities to local transportation companies, reduced traffic congestion, implementing safety mechanism in transportation and automation of loading and unloading. Substituting the use of information technology for transportation is also an evolving CSR practice in logistics and transportation (Feitelson, 2002).

Storage and Warehousing

Social responsibility in warehousing commences right from selection of an appropriate location considering relevant environmental and social parameters. Companies storing hazardous materials, such as, chemicals, should take special measure for environment safety. Necessary safety measures for securing worker’s health and safety is also an important CSR imperative (Ciliberti *et al.*, 2008).

CSR Indicators

In 1990s, database methods were used for measuring CSR activities. The Kinder Lydenberg, and Domini (KLD) (see “Relevant Websites section”) evaluates companies based on nine dimensions: the environment, military contracting, employee relations, community involvement, product safety, quality programs, excessive compensation of executives, diversity and nuclear power. Another database measure that was extensively used was CSID (see “Relevant Websites section”), which calculates the sum of the average of a firm’s strength and weakness focusing on seven dimensions: community, employee relations, environment, diversity, product and business practices, international operations and corporate governance. The limitation of these databases

is restricted use of these to certain countries only. Besides these databases, various researches in literature have proposed one or more of the following CSR measurement approaches (i) pollution indices (Igalens and Gond, 2005) (ii) organizational reputation indicators (Igalens and Gond, 2005; Turker, 2009) (iii) perceptual measures derived from surveys (Igalens and Gond, 2005; Maignan and Ferrell, 2000) (iv) content analysis of annual reports (Igalens and Gond, 2005; Turker, 2009) (v) data produced by research organizations (Igalens and Gond, 2005), and (vi) single- and multiple-issue indicators (Maignan and Ferrell, 2000; Turker, 2009).

The major limitation of pollution control indicator is its unidimensionality. In reputational measures, the sample is usually business students, corporate staffers or experts that evaluate a given number of organizations mentioned in the questionnaire. This limits the number of organizations rated because usually the respondents cannot rate more than 20–30 companies at a time. A similar limitation exists in surveys also. In content analysis of annual reports and organization's publications, the CSR score is derived from the percentage of lines, words, or pages in reports related to corporate social activities. Since the method relies totally on self-disclosure of information in company reports, the analysis may not be considered fully reliable. Regarding the multiple indicators approach, there is no agreement regarding appropriate number and type of indicators used worldwide. Some of the widely used measures include: The Jantzi Social Index (see "Relevant Websites section") measures performance of Canadian companies in social areas such as aboriginal relations, community involvement, corporate governance, employee relations, the environment and human rights and introduces more than 200 indicators, the JSE SRI Index (see "Relevant Websites section") includes 71 indexes which further consists upto 9 sub-indicators and the Dow Jones Sustainability Index (DJSI) (see "Relevant Websites section") comprise over 48 indicators and proposes both general and sector-specific indicators to include the specific challenges and trends of each sector.

Jantzi Social Index does not include companies involved in production of nuclear power, manufacture of tobacco products and weapons. DJSI does not include sectors involved in alcohol and tobacco production and gambling. JSE SRI Index takes into account all types of sectors in the measurement procedure. There are more indexes used in different countries with the limitation of its usage in particular types of economies or countries only. Thus, it can be said that there is no universal agreement regarding usage of indexes. Moreover, most of the measures suggested above comprise CSR indicators in context of the organization's domain with very less or no focus on the organization's upstream and downstream players. Thus, the present paper suggests holistic and integrative set of CSR indicators for the organization's supply chain.

In this regard, a series of studies conducted in understanding responsible businesses in an emerging economy like India, hold important lessons for developing CSR indicators in supply chains. Interchangeability of CSR and sustainability definitions, lead to four broad categories of measurement, namely- Sustainability, Governance, Disclosure and Stakeholder Management (see "Relevant Websites section") (Also refer Majumdar *et al.*, 2015).

The Sustainability category comprises of environmental and social dimensions. Within these, the environmental dimension includes, waste, water, energy and emissions management. It also includes, incorporation of biodiversity objectives, environmental compliance and environmental management systems in firms and supply chains. The social dimension includes employment, occupation health and safety, labor relations, training and education, non-discrimination, diversity and opportunity, community involvement, customer and worker health and safety.

A summary of the composite index discussed in the section below, is provided in Table 1.

Sustainability

Environmental dimensions

Water as an indicator relates to groundwater usage, percentage of water used versus received, marine water protection, water abstraction etc. Energy indicator includes energy efficiency of entities in the supply chain, energy usage in production processes, percentage of renewable energy used etc. Waste indicator includes hazardous emissions, recyclability of wastes, toxic chemicals discharge, landfill waste, amount of waste being incinerated etc. Emissions include CO₂ emissions, other greenhouse gas emissions. Measures of biodiversity include protective measures of forestland, habitat protection, wildlife protection, land usage etc. Lastly, environmental management systems and compliance include adherence to ISO14001 measures, implementation of environmental management systems, and audits in supply chains.

Social dimensions

Social indicators in training and development category include demonstrated responsibility of senior management for training and development, training and development programs for organization's employees, annual budget for training, hours spent on training, developing and carrying out training programme for suppliers, procedures for assessment of training and development effectiveness of supplier's training. Occupational health and safety include physical and psychological working conditions in compliance with rules and regulations of national and international standards, compliance with industry health and safety rules and regulations, details of appropriate policies and procedures of implementation of employee health and safety measures, coverage of certified health and safety systems, screening of suppliers based on health and safety procedures implemented, number of random inspections at suppliers premises and warehouses for checking physical and psychological working conditions, number of random inspections at suppliers premises and warehouses for checking health and safety systems implementation etc.

Table 1 Composite CSR Index

<i>Index</i>			
<i>Sustainability</i>	<i>Governance</i>	<i>Disclosure</i>	<i>Stakeholder Management</i>
Environmental Objectives:	Top management overview of CSR and sustainability initiatives.	Report activities and disseminate information through financial and non-financial measures.	Inclusive business and supply chain considering diverse objectives of customers, suppliers, employees and communities.
Waste	Managerial accountability of responsible business measurement and reporting.	Adherence to reporting standards such as Global Reporting Initiative (GRI) standards.	
Water			
Energy	Availability of formal CSR and sustainability policies.		
Emissions			
Biodiversity	Adherence to international standards on CSR activities and reporting.	Participation in international projects such as Carbon Disclosure Project (CDP).	
Environmental Compliance			
Environmental Management Systems	Existence of management systems to continuously benchmark firm and supply chain performance against international standards.		
Social Objectives:			
Employment, Occupation health and safety			
Labour relations, Training and education			
Non-discrimination, diversity and opportunity, Community involvement, Customer and Worker health and safety			

Diversity and opportunity category include establishing procedures and mechanisms for providing equal opportunity to all employees, number of women in lower, middle and senior level management, number of people with disabilities employed, value statements of the organization making diversity a core value, established procedures and mechanisms for monitoring all suppliers, number of diverse suppliers of various geographic regions, collaborations and partnerships with industry groups to increase the diversity of supply chain. Community involvement includes annual monetary donations for community upliftment, gifts in kind, payroll schemes, etc., details of the community projects supported, organization's policy on community participation in administration and management, level of community participation in administration and management and decision making. Customer and worker health and safety includes procedures in place to ensure safe storage of products under appropriate conditions, packaging to protect product from deterioration, appropriate labeling on product packaging indicating contents, procedure to use and store the product, compliance with product safety regulations, number of product recalls, use of information technology for supplier management, tools and techniques employed for traceability of the flow of raw materials, parts for assembly and finished goods, assessment of supplier systems to consistently deliver products that meet certain safety and quality standards and so on.

Governance

Governance includes top management overview of CSR and sustainability initiatives, managerial accountability of responsible business measurement and reporting, availability of formal CSR and sustainability policies, adherence to international standards on CSR activities and reporting, existence of management systems to continuously benchmark firm and supply chain performance against international standards (Majumdar *et al.*, 2015).

Disclosure

Disclosure relates to the ability to report activities and disseminate information through financial and non-financial measures (some of the measures have been discussed in the previous paragraphs), adherence to reporting standards such as Global Reporting Initiative (GRI) standards, participation in international projects.

Stakeholder Management

Lastly, stakeholder management includes ability to have an inclusive business and supply chain considering diverse objectives of customers, suppliers, employees and communities (some of the measures related to multiple stakeholders have been discussed earlier). Including these multiple and often diverging stakeholder centric views to design and implement supply chains is considered in stakeholder management category.

In what follows, we discuss various cases of firms which have attempted to incorporate CSR initiatives in their supply chains.

Case Studies in CSR Initiatives

Corporate social responsibility, or CSR, has assumed great importance for the textile industry in recent times. One of the chief reasons for this renewed importance is the linkage of this industry with the fashion industry, which has realized the need to be more sustainable in future. Another reason is the multiplicity of the stakeholders in this industry, such as, consumers, suppliers, manufacturers, designers, retailers, unorganized boutiques, employees, governments, regulators, export-import regimes, trade blocks, non-governmental organization, society, media, public relation groups, etc. It is clear that such multiplicity of stakeholders, and their complex interactions, put enormous pressure on the textile businesses to act and appear socially responsible. Additionally, it is crucial for the textile industry that implementation of environmentally and socially sustainable policies are spread across the entire production chain.

Corporate social responsibility efforts greatly benefit the companies in this sector by enhancing brand recognition, recognition, global reputation, and even, employee morale on a global scale and greater opportunities to attract better and more qualified staff. However, it can also be quite challenging for the organizations in this industry because of the global nature of their supply chains. Such challenges include different tariff zones and diversity of cultures. Thus, most organizations in this industry tend to focus on short-term profit gains rather than long-term sustainable efforts like CSR (see “Relevant Websites section”).

In the sub-sections below, we briefly highlight CSR efforts of some of the salient organizations in the textile industry.

Zara

Inditex, the parent company of the famous brand Zara, has aligned itself with the seventeen Sustainable Development Goals (SDG) of the United Nations, and its targeted themes of people, prosperity, peace, planet and partnerships. Its recycling initiative, aptly called Closing the Loop, encourages customers to deposit their used garments in the retail stores for an incentive. An explicitly stated goal of Inditex is that, by 2020, they will not need to direct any material from their headquarters, distribution channel partners, or factories to the landfills. The company also uses the Greenhouse Gas Protocols for the measurement and reporting of carbon emissions, which guides their goals of the reduction targets. The company also has plans to reduce their water footprints through a master plan. It lays great emphasis to ethics, which involves setting criteria for wage rates, employee empowerment, supply chain transparency code of conduct. For instance, Inditex has instituted a complete ban on child labor, or bonded labor. It has a strong animal welfare policy which puts a strict ban on fur, angora or the products tested on animals.

Some salient actionable pointers of the Zara’s CSR policy are listed below:

- A Teaming programme, through which its employees can donate a fixed amount of their salaries to initiatives of social organization like Red Cross and Oxfam
- Profit-sharing plan for employee’s benefit
- Participation in community service projects
- Implementation of newer and better health and safety standards for clothing, footwear, accessories, cosmetics or food-based products.
- Implementation of EPGO programs (Educate People, Generate Opportunities), which invests in education and training for employment of vulnerable groups, such as displaced or refugees
- Instituting an honorary award “Inditex Chair Professors Funding” for outstanding research scholars from Emerging Markets Institute

Patagonia

Patagonia, a California, U.S.-based company, which specializes in outdoor apparel, has taken a rather unconventional route for CSR activities. Sustainability and caring for the environment are the key to the core values of the company, and drives its vision and missions. Patagonia has been donating a huge amount of money to the nonprofit and environmental groups since its inception. Additionally, it has a number of social ventures, and a countless number of volunteer hours by its employees.

Some key indicators of the Patagonia’s CSR efforts are listed below (Zurn, 2017):

- Membership of The Planet (an alliance of businesses), through which Patagonia gives 1% of its sales to the preservation and restoration of the natural environment.
- Donations to nonprofits through an Employee Charity Match programme
- Employee volunteer hours
- Establishment of FootPrint Chronicles, an interactive newsletter and map, which provides a complete picture of its supply chain
- Publication of Environmental and Social Initiative Report, and an online database which gives the breakdown of grants, campaigns, events, sustainability and fair trade efforts, materials selection, etc.
- Patagonia effectively uses social media and online communities to create awareness on ethical issues like #ProtectBearsEars
- In collaboration with their suppliers, production of organic cotton certified by the Global Organic Textile Standard (GOTS)
- Effective recycling programs for polyester, nylon, and wool, thus rejecting fast fashion by creating high-quality, and long-lasting products. Patagonia even attempts to discourage customers from purchasing too many of their products.
- Good labor policies with a view of payment of minimum wages, transparency, and worker empowerment.

- An effective Supplier Code of Conduct, with provisions for tracing and auditing the entire supply chain across vendors and sub-contractors.
- Strong animal welfare policies, with no use of angora, leather or fur; and encouraging used of recycled wool and down feather, accredited by the Global Traceable Down Standards
- Common Threads Initiative, which promises recycling and repairing free of charge.

Levi's

For a number of years, Levi's brand name has been synonymous with the counterculture and effortless style. However, such brand positioning and a mammoth global production scale has not prevented the denim giant Levi's to heed serious thought to the growing importance of CSR concepts, and relatedly, to ethics and sustainability. The company realizes that the decisions taken in this regard by itself, a manufacturing giant with its marquee products of blue denim, will have far-reaching consequences in this industry. Indeed, the Levi's 1991 document, titled 'Terms of Engagement,' which reflects a code of conduct reference for ensuring ethics in the production through its supply chain, is claimed to be a landmark and has exhorted several apparel companies to develop a similar reference document for their organizations.

Some salient pointers of the Levi's CSR efforts are illustrated below (see "Relevant Websites section"):

- A product life cycle analysis of Levi's demonstrated that, for the, Stonewash Jeans, one of its marquee products, a significant proportion of the climate effect and the consumption of water resources occurred during the crucial phase of consumer care. Levi's took a vital cue from this research result and has tried to shift the attitude of consumers from fast-fashion consumption to treat Levi's jeans as a long-term investment.
- Levi's is highly committed to the production of denim under sustainability norms, and have tried to significantly reduce their water use, under its Water<Less™ programme. It is also a prominent participant of the Better Cotton Initiative.
- Levi's has set up stiff reduction targets for greenhouse gas and electricity consumption.
- In 2012, Greenpeace organization launched an aggressive campaign, labeled 'Toxic Threads', against Levi's for the water pollution caused by the company in Mexico. Levi's constructively responded to the issue and vowed and took action for the reduction of the hazardous chemicals used in the dyeing and treatment of their apparels.
- Levi's has a good record in human rights and worker welfare.
- Levi's traces and audits its entire supply chain on key CSR parameters over an extended period.
- Levi's does not use fur, angora, shearling, karakul or other exotic animal skin or hair. Their Animal Welfare Policy ensures that the processes of all supply chain partners are traceable and transparent to ensure animals welfare. Levi's sources its wool raw material from the certified non-mulesed sheep.

Conclusion

Stakeholder expectations from firms and supply chains have led to evolution of responsible businesses in several cases. In particular, CSR has evolved from a voluntary initiative to a strategic decision for firms with organizations increasingly looking to incorporate CSR in their boardroom decisions. However, measurement and reporting of CSR is still evolving with different CSR indexes being used. In this study, we provide a holistic overview of CSR indexes while integrating sustainability dimensions with CSR.

For several organizations, CSR remains a voluntary initiative. However, for many firms, owing to changes in government policies, CSR has become a mandatory activity. Further, pressure from other stakeholders such as consumers, non-governmental organizations, media, communities etc., have also made it difficult for firms to work in silos without integrating environmental and social objectives. Geographically spread supply chains have the potential to cause significant negative impact on environment and communities, if not monitored. A supply chain centric view in this regard, helps firms work with other partners in the supply chains beyond the boundaries of their own organization.

In this context, the paper discusses several objectives that can be integrated in CSR measures of supply chains. The paper addresses the difficulties that firms face in reporting CSR activities, specially the non-financial measures. The paper also illustrates the incorporation of CSR activities in supply chains through various case studies.

There are several directions for future research that emerge out of this discussion. There is a scope of empirically validating the CSR measures and analyzing the reporting practices of global firms. Further, analytical models to understand the economics of CSR effect on firms and supply chains could also provide several insights. Studying the impact of CSR policy changes on industry sectors is another area in which further research can be conducted.

Cradle-to-Cradle Versus Consumer Preferences in the Fashion Industry

Claudia E Henninger, Marta B Cano, Rosy Boardman, Celina Jones, Helen McCormick, and Shahd Sahab, University of Manchester, Manchester, United Kingdom

Introduction

Sustainability is not a new phenomenon, but rather has been discussed since the 1980s when the Brundtland Commission (WCED, 1987) formulated one of the most iconic definitions of the term highlighting that the needs of the current generation should be met without compromising opportunities to meet future generations' needs. Although heavily criticized and debated, this definition remains to date the most cited in the literature and provides an initial insight into key priorities. The report indicates that industries and consumers should change their current practices to become more sustainable, thereby providing an outline of what sustainability is. This implies that the Brundtland Commission's report (WCED, 1987) leaves room for interpretations to be made by key stakeholders in the industry and consumers as to how they can contribute to a more "sustainable" world and what they deem fit to change. Sustainability to date remains a key topic, and, particularly within the fashion industry, has become a buzzword, as societal and environmental issues are increasingly emerging through negative media headlines.

Sustainability is a key driver for innovation that encourages out-of-the-box thinking and avant-garde behavior by finding new solutions and possibilities to produce and create products/services that the current generation may need without exploiting the social, environmental, or economic environment. Thus, it is guaranteeing a future for generations to come. A key issue in the 21st century is waste, with unwanted garments being discarded in landfill – in the UK this equates to 300,000 t annually (WRAP, 2017). Although this number has significantly decreased since 2012, when 350,000 t of garments were binned, this still raises concerns, especially since "industry, innovation, and infrastructure" and "responsible consumption and production" are two of the 17 top priorities to be addressed by the United Nations (UN, 2018). To put this into further perspective, garments that are simply binned in the household waste account for 5.7% of solid waste in landfill, a figure that is rather substantial and could be dramatically reduced in the future (Weber, 2015).

A current challenge faced in the 21st century is the fact that "we think of materials in a 'human timeframe,' when actually they can relate to materials which in some cases took millions of years to form (and will take hundreds of years to decompose). We need longer term thinking" (Goldsworthy cited in Gould (2015)). A majority of materials take longer to decompose than a human lifetime (if at all). This implies that waste products remain for our future generations to deal with. This is an issue that does not fit with the Brundtland Commission's vision of a sustainable future. Although there are fashion companies that are more forward thinking, such as the Swiss manufacturer Freitag, who has developed a fully biodegradable pair of jeans, the fashion industry as a whole needs to considerably change, as current business models are unsustainable. Thus, this article focuses on cradle-to-cradle versus consumer preferences in the fashion industry, providing key definitions and valuable insights into the topic area of the circular economy.

Cradle-to-Cradle

Cradle-to-cradle is a design principle that sees waste as a new resource and thus works on the basis of designing for a circular approach that reloops materials. This implies that products are designed in a way that make it more cost effective to recycle them rather than purchasing new materials and thus, create less waste (McDonough and Braungart, 2002). The cradle-to-cradle design principles fall within the circular economy. The latter is defined as "looking beyond the current take-make-waste extractive industrial model [...] and] is based on three principles: (1) design out of waste and pollution; (2) keep products and materials in use; (3) regenerate natural systems" (Ellen McArthur Foundation, 2017). The origins and implications of cradle-to-cradle are further explored in the following.

The majority of current industry practices adhere to a linear economic model that is based on transforming raw materials into a product then distributing the product to the consumer until it reaches the end of its "useful" life. To explain, it is a one-way approach that is not necessarily concerned with reducing environmental and societal impacts. Rather it is solely focused on creating products that are one-off items that enter the supply chain as raw materials and exit as postconsumer waste products. The circular economy challenges this system's thinking approach by moving away from the linear economic model towards one that is regenerative in nature and based on closed loop systems (Niinimäki, 2017). As such, the circular economy provides an opportunity for manufactures and suppliers to rethink their current practices by strategically planning how their products/services can be reused. The RSA Action and Research Centre (Royal Society for the encouragement of Arts, Manufacturers and Commerce (RSA Action and Research Centre, 2016)) identifies four possibilities of fostering the relooping process, by designing for (1) longevity, (2) leasing or service, (3) reuse in manufacture, and (4) material recovery.

The origins of the circular economy can be found in the cradle-to-cradle principle developed by McDonough and Braungart (2002). Cradle-to-cradle takes three core aspects from nature in that everything can be used as a resource; this indicates that waste materials can

be utilized as raw materials for another product and relooped into the system. As such, products can either enter the biological cycle or the technical cycle.

Biological Cycle

The biological cycle implies that products are created with design in mind, indicating that anything can be designed to decompose into soil at the end of the life cycle. Although biodegradability or the biological cycle could be seen as an ideal option, as no waste would be produced with fabrics and/or fibers dissolving into a natural product (soil), there are various challenges associated with the biological cycle. To explain, some argue that it is not possible to have fibers and textiles biodegrade safely. Firstly, textiles need certain conditions to biodegrade, which are usually not found within nature. Secondly, the majority of garments are cultured and treated with chemicals that, in a state of biodegradation, would filter into the natural environment and could cause harmful damage (Niinimäki, 2013). As such, it is questionable whether the biological cycle can be regarded as an option of relooping, especially within the fashion industry. Whilst biodegradability could overcome a current challenge of textile waste in landfill, more research would need to be done to explore how to hinder the harmful substances with which materials are treated, to enter the natural environment. To explain, a question that needs to be addressed is what the better option entails – reusing recycled materials or virgin materials, by assessing their impact on the natural environment through, for example life cycle assessment of energy use, recyclability of the end product, and overall use of chemicals.

A further challenge in relooping textiles and fibers concerns the composition of our garments. The majority of garments currently in the market are made from mixed materials, such as natural and synthetic fibers. A majority of these cannot be recycled as these fibers cannot be separated/split into their original components. Moreover some recycling processes are simply too costly to be introduced as mainstream practices, which implies that it would be cheaper for manufacturers to use virgin materials, rather than to reloop textiles.

Technical Cycle

The technical cycle on the other hand repurposes and reuses high quality materials for new products. The technical cycle of relooping textiles and garments could be seen as the best option within the fashion and textiles industry. To explain, harmful chemicals are not released into the natural environment, but rather fibers are broken down and reused without contamination (McDonough and Braungart, 2002). Yet, a key challenge here is the current fast fashion model, which is dominating the industry. The fast fashion model is based on, as indicated in the name, fast stock turnover at an increasingly low cost, which also affects the quality of the raw material used (Rutter *et al.*, 2017). It can be argued that consumers have been educated to develop a fashion appetite that almost forces industry players to cut corners to supply cheap garments (Sharma and Hall, 2010). However, this has both environmental and social implications whilst simultaneously decreasing the quality of the products. The latter has a knock on effect for the industry, as the cradle-to-cradle process is reliant on good quality raw materials to be looped back into the supply chain and reused for new products. As such, if the quality of garments is decreasing then the quality of the raw material may not be up to standard, and thus, cannot be reused in the relooping process.

Cradle-to-Cradle Barriers

The cradle-to-cradle approach provides a foundation for the circular economy, which challenges the current system's thinking approach of linearity, by encouraging the industry to consider designing products for circularity. Yet, as indicated in the previous sections there are key barriers garment manufactures face, which are linked to both the biological and the technical cycle. Although the 21st century has seen an increase in technology and new innovations, they (technology, innovations) still lack the ability to split mixed fibers into individual components and hinder chemicals used in the dyeing process to be released in the natural environment. Furthermore, with businesses focusing on a quantity over quality approach, raw materials cannot be relooped (Niinimäki, 2013, 2017). More research needs to focus on the feasibility of the cradle-to-cradle approach especially within the fashion industry and explore viable options to move forward to a more sustainable future.

Consumer Preferences

When considering introducing a cradle-to-cradle approach, organizations must firstly consider their customer's preferences. Customer preferences indicate the level of demand for their products, and indirectly determine whether this is a feasible business option. Customer preferences are especially vital within the fashion industry, as fashion is much more than simply clothes that follow trends. Garments showcase our personality by representing which social groupings (e.g., hipster, punk, Goth, upper class) we belong to and by highlighting a desire to be unique and creative. Fashion visualizes our identity to the outside world and makes a statement about who we are, how we see ourselves, and who we want to be in the future (aspiration) (Myzelev, 2013). Clothing is used as a vehicle of self-presentation whereby an individual can defend, maintain, and create multiple identities in an attempt to align oneself with perceived social norms. Social norms are unwritten rules of behavior that are considered to be acceptable by society and/or groups

within (McNeill, 2017). Unsurprisingly clothing consumption in a postmodern world is a crucial element in the construction of identity and the self and vitally important for individuals (Niinimäki, 2010; Tiggemann and Andrew, 2012).

From a marketing perspective, consumer preference refers to the likelihood of an individual purchasing one product over another. This is based on subjective value indicators that are dependent on an individual's personal taste, cultural influencers, their education, and reference groups. The latter aspect is linked to the theoretical concepts of self-esteem and self-concern, as individuals seek to be part of an "in group" to satisfy their needs of belonging to a specific "in group" (e.g., reference group) (Millan and Mittal, 2017). Self-esteem is defined as an individual's evaluation of themselves, which can either be positive or negative, and thus determines their own worth, value, and importance. As such, consumer preference is influenced by how a product, in this case a garment and/or accessory, makes them feel about themselves. Today's society is driven by hyper consumerism and an "I want this now and cheap" phenomenon, often referred to as fast fashion. As such it may be challenging for organizations to break consumer habits of wanting to purchase new items at an increasingly rapid speed. Although garments and textiles, especially in the technical cycle, are "new" they could be perceived to be produced from postconsumer waste, and as such have a negative connotation. Similarly, the self-concept is defined as the totality of a person's thoughts, feelings, and attitudes towards oneself (Goldsmith *et al.*, 1999). Rosa *et al.* (2006) found that consumers seek to affirm their self-concept through the use of apparel. Thus, to increase the saleability of sustainable garments, they must appeal to a consumer's self-concept and boost their self-esteem. The notion of acting responsibly is not the sole driver when buying clothes, which further highlights that there is an attitude-behavior gap of people wanting to do something versus actually acting upon it. Self-esteem and self-concept are linked to self-concern, which focuses on the individual's desire to either keep up or achieve a desirable standing within their social group and/or society, and thus gain respect from others (Henninger *et al.*, 2017; Millan and Mittal, 2017). This suggests that if consumer's peers start acting more socially responsible and are shopping more sustainably, then they are likely to follow suit. Hence, making sustainable purchases has the potential to act as a status enhancer, as individuals may want to be seen as being more "green" and making a conscious choice of consuming in a more environmentally friendly or socially responsible manner. This idea does seem to be having some effect, as one-fifth of consumers now say that they prioritize sustainability when shopping for clothes (Drapers, 2018). Furthermore, this sentiment has been capitalized on by certain brands by becoming 100% fur and leather-free and/or creating animal rights campaigns for sustainable consumption. Examples of companies are Stella McCartney, Ralph Lauren, Calvin Klein, and Tommy Hilfiger. This highlights that there is a shift within the industry that clearly aligns with the goals set by the United Nations. With major brands jumping on this bandwagon, the idea of making sustainable and/or ethical clothing "cool" is a concept that is not so far removed anymore. As such, it can further push the cradle-to-cradle paradigm to not only be a viable option in the future, but also to be the best option in terms of business model development. Consumers have the ability to make or break a business, by changing their own practices and demanding a different way of production organizations can be almost "forced" into changing their current business models.

Yet, the attitude-behavior gap remains to be a significant challenge when it comes to purchasing sustainable garments. Despite a positive intention to purchase more sustainably, the appetite for fast fashion is thriving. Online fast fashion retailers such as Boohoo.com and Prettylittlething.com record a continued year-on-year sales increase. These companies have moved from a fast fashion paradigm to a hyper fashion one, implying that stock turnover has been reduced to a one-week turnover (Geoghegan, 2018). Furthermore, the lack of availability of sustainable products or the perception that sustainable garments are not trendy or fashionable enough may be reasons for not purchasing them. This further increases the attitude-behavior gap. For some consumers, ethical purchases will only take place if there is no perceived real or imagined cost, in terms of added price or loss of quality. Currently there is still a perception that products, especially garments that are more "sustainable" come at a higher cost, and thus, may no longer be affordable (Rutter *et al.*, 2017). While concern for the environment and society at large are key drivers for making ethical purchasing decisions, egoistic motivations such as value for money, image, or well being have an even bigger influence on purchasing decisions. This makes it difficult to justify a high price for ethical garments (Jägel *et al.*, 2012). In line with this, there appears to be a general lack of consumer awareness around sustainability issues in the fashion industry. Consumers are unaware of the difference that engaging in ethical behavior could make, in terms of an environmental and social impact (Shen *et al.*, 2012). This implies that more needs to be done by educators and marketers to decrease the attitude-behavior gap and educate consumers about the impact the fashion industry has on the environment and society as a result of hyper fast fashion production and consumption.

What is apparent from the previous discussion is that marketing and especially marketing communications are vital in influencing consumer preferences, through appealing to a consumer's self-esteem and self-concept. The way that organizations broadcast their messages on the circular economy needs to be clear and coherent to create customer buy-in that can foster a decrease in the attitude-behavior gap and fully capitalize on the United Nations' sustainable consumption and production goals through, ideally, a cradle-to-cradle business model (Niinimäki, 2010; Henninger, 2015). Yet, whilst customer preferences may be an indicator for customer demand there are other aspects that can further influence an individual's choice, such as availability, pricing, and associated value.

Conclusion

Although this article might be seen to set out a bleak backdrop on current practices in the fashion industry, by highlighting that a cradle-to-cradle approach may not necessarily be feasible, especially as it faces challenges through the attitude-behavior gap, there are positive outcomes that can be observed.

Despite negative media, the fashion industry is changing, with one of the biggest changes being that we can now observe the normalization of sustainability across the industry. Organizations within the fashion industry are increasingly adopting and developing sustainable policies that align with the United Nations' goal of "sustainable production and consumption," whilst furthermore setting "sustainable" performance indicators, such as using sustainable raw materials and/or recycled fibers or design for longevity, and other mandates. All of these aspects can be linked to a cradle-to-cradle design process and more specifically the circular economy. Although challenges remain with current practices that can be observed within the fashion industry, they clearly highlight a step into the right direction and promote an optimistic outlook for the industry as a whole.

The article highlights that more needs to be done to educate and inform consumers about the consequences of their consumption decisions on the natural and social environment. This could help to further reduce the attitude-behavior gap that remains in the current society. As such, the role of marketing communications is important to influence consumer preferences (specifically the self-concept and self-esteem) and purchase decisions. Communication needs to come from different angles and different media, as fashion consumers gain their information from a variety of sources (e.g., communication channels). Thus, fashion retailers and specifically fast fashion retailers should clearly communicate their sustainable practices and approaches to a more responsible production processes. Consumers need to understand what the real benefits are of sustainable products, to make an informed decision, and how they can get access to them. The overall offering of sustainable fashion products needs to increase for consumers to be able to make a choice. Sustainable brands, especially those aligning with the cradle-to-cradle model should not be perceived as being niche and expensive, but rather as the best option.

Social media has become a very influential communication channel that allows users to broadcast messages within real time to a truly global audience. Different social media platforms (e.g., Facebook, Twitter, Instagram) have been used to facilitate dialogic communication between different stakeholders and to popularize sustainable fashion on a wider scale. Examples that can be brought forward are the Campaign for Clean Clothes, which actively promotes sustainable fashion practices, as well as the nonprofit organization Labour Behind the Label, which manifests for more accountability and transparency within the fashion and textiles industry, thereby calling on organizations and consumers alike (Rutter *et al.*, 2017). Currently fashion brands are not fully capitalizing on the communication channels available to them, which indicates that they need to provide more information within their advertising and promote the benefits of sustainable fashion and the cradle-to-cradle approach for consumers to make better ethical judgments (Rutter *et al.*, 2017). Having clear marketing communications based on transparency has the potential to not only influence but also change consumers' preferences. To reiterate this further, some campaigns do have a strong effect on the promotion of cradle-to-cradle and circular economy practices. Fashion Revolution has contributed to give visibility and increase awareness about movements and initiatives related to a more responsible and conscious approach to fashion, demanding responsibility from retailers and consumers.

Eco-Innovation Options in Food Processing

Serenella Sala, European Commission, Joint Research Centre (JRC), Directorate D – Sustainable Resources, Bio-economy Unit, Ispra, VA, Italy

© 2020 Elsevier Inc. All rights reserved.

Introduction

The challenge for developing a “green production-oriented economy” relies on the definition of sustainable production and consumption patterns, which can enlarge the current approach oriented to the greening of single production as opposed to the creation of a comprehensive sustainable production system. The food we grow, harvest, process, distribute, trade, and consume plays a vital role in the connection between people, planet, and prosperity (UN, 2016). Since food production and consumption are considered two primary sources of environmental impacts, eco-innovations addressing the food system are crucial to sustainability. International resolutions widely highlight the necessity of a more sustainable approach to production and consumption patterns as an essential element to promote sustainable daily life activities (see, for instance, UN SDGs) (UN, 2015). Ensuring sustainable human development means being able to feed a planet with increasing population, decoupling the socio-economic development from the environmental impacts (UN, 2015).

Food supply chains are increasingly associated with environmental impacts while showing both positive and negative socio-economic implications. An increasing global population, with associated increasing in food and energy consumption, an evolution in consumers’ needs, and changes in consumption models pose serious challenges to sustainable production and consumption of food. Life cycle thinking (LCT) and in particular life cycle assessment (LCA) are powerful analysis methods that scientist leverage in their quest for solutions to major food-related global challenges.

In fact, as impacts occur along the food supply chain (agriculture, manufacturing, distribution, retail, consumption, and end of life) (Notarnicola *et al.*, 2017), the LCA method can support the identification of eco-innovations and the comparison of options with a plausible impact on those innovations. Hence, industrial ecology approaches, LCT and LCA are increasingly considered in order to re-think current production and consumption patterns (Sala *et al.*, 2013), especially in support of a transition towards a bio and circular economy. This life cycle perspective reflects the widespread of sustainability science as a solution-oriented discipline that requires the integration of methodologies towards concrete and positive actions. In 2017, a collection of studies on food impact assessment and possible solutions has highlighted that nutrient recovery, resource efficiency, enhanced food waste management, better governance and cooperation among the actors along the entire supply chain are at the heart of the environmental sustainability and innovation of food systems (Sala *et al.*, 2017).

The introduction and adoption of green technologies are regarded as the most cost-effective path to reduce environmental pressure without compromising economic competitiveness, even though quantitative empirical findings on the effectiveness of green technologies in improving environmental performance are scarce (Costantini *et al.*, 2017). However, acting on technological aspects is not enough, and social aspects (from consumer behavior shifts to engagement of stakeholders along the food chain) are also crucial.

Recent theories evolving from the so-called “sustainable transition” towards “substantial system changes” (Dentoni *et al.*, 2017) suggest that in order to accelerate such a transformative turn, change agents or stakeholders should seek coherence among actors co-creating knowledge, mutually supporting interventions, intervening at technological, organizational, and behavioral levels, and enforcing changes. Trends of innovation in the food industry are deeply affected by cultural heritage, habits, and institutional contexts (Savino *et al.*, 2018).

This article presents a state-of-the-art review of eco-innovations in the food chain and discusses a structured approach for their identification and the evaluation of their environmental benefits. LCA is a reference method for the identification of eco-innovation needs and the comparison of eco-innovation options. Indeed, LCA can be applied for defining solutions to major food-related global challenges and specifically for the identification of eco-innovations, their impact across all the stages in the food supply chain, and the comparison of options for food supply chain optimization. Eco-innovation is often implemented in the assessment of environmental gains and possible trade-offs. Eco-innovations include technological improvement, behavioral changes, and the assessment of potential changes in eco-innovations under different environmental conditions (e.g., climate change).

Identification of Eco-Innovations

The use of LCA is crucial to assess the sustainability of the food sector and food supply chains. LCA may be complemented with more site-specific methods (e.g., to address the intrinsic variability of food systems at any stage from agriculture to food manufacturing stages) or with a study encompassing categories of impact usually not covered by LCA (e.g., impacts of invasive species, or of genetically modified organisms). In a comprehensive study, the assessment of a basket of food products (with more than 30 products) unveiled the environmental impacts associated with the consumption of food in the European Union within 16 impact categories and for all life cycle stages (Notarnicola *et al.*, 2017 and related updates, such as Castellani *et al.*, 2017a). This study used a bottom-up approach, based on the selection of representative food products and related life cycle inventories. The method defined a baseline scenario modeled in consideration of the statistics on food consumption by the average European citizen. Such baseline scenario was leveraged as a reference in the evaluation of potential improvements from eco-innovation and behavioral changes.

The majority of studies in the literature highlight the high contribution of all the life cycle stages of the food production chain to Greenhouse Gases (GHGs) emissions. Such contribution is due mainly to the emissions in the agricultural stage and in the end of life, e.g., from landfill (food wastes in landfills emit large amounts of methane – which results in a high global warming potential – and carbon dioxide), and the use of energy during production (from agriculture – including land use change – to processing, manufacturing, transportation, storage, refrigeration, distribution, retail, and consumption) leading to climate change impacts. However, more comprehensive studies inclusive of diverse impact categories beyond climate change (such as ecotoxicity, eutrophication, or land use) are being published. In these studies, climate change, land use, water use, ecotoxicity, eutrophication, and acidification appear as leading impact categories. Recurrently cited impacts associated to the above-mentioned impact categories include the alteration of biogeochemical cycles of N and P – e.g., used as fertilizers in agriculture –, loss of soil quality due to land use, and loss of biodiversity due to land transformation for food and feed cultivation, loss of biodiversity due to the use of pesticide, and water consumption by agriculture and food manufacturing.

Regarding life cycle stages, agriculture usually contributes more than 70% of the overall environmental impacts, followed by end of life, which generates eutrophication impacts due to the human metabolism of food (i.e., wastewater treatment), and industrial processing, especially for what concerns energy-related emissions and water depletion. Assessing the relative importance of consumed food products, those related to animal husbandry and related feedings, such as beef, pork and poultry meat, and dairy products result in a higher impact.

Indeed, specific food sectors generate higher environmental impacts than others. Beef, butter, and cheese generate higher environmental burdens, primarily related to their carbon footprint and material intensity. On the contrary, vegetables, cereal products, potatoes and fruit such as apples, when consumed in their season, generate much lower impacts. These higher environmental burdens are confirmed by meta-analyses that have collected large bodies of LCA studies to draw general conclusions on the hierarchy of impacts across different food categories. On GHGs emissions, these studies reach similar conclusions in identifying animal-based products (and in particular beef meat) as those responsible for the largest emissions while fruit, vegetables, and grains result in the lowest impacts. Within the livestock sector, feed production is a relevant source of impact.

Very often eco-innovations are associated with the food processing or product itself but do not consider packaging (e.g., for a beverage bottled in glass), even though packaging often becomes the factor leading to major environmental impacts.

Most of the studies in the literature address the environmental assessment of single products, but only a few studies adopt a consumption-oriented approach that assesses the impact of food supply chains in large geographical areas. However, studies at both meso- and macro-scales are fundamental in providing decision makers with data for an informed transition to sustainable production and consumption patterns, and to decouple environmental impacts from responses to societal needs while ensuring economic growth.

At the macro scale, environmental impacts associated with consumption have traditionally relied on a ‘top-down’ approach by using the sectorial economic information of input-output tables. The macro-scale approach often calculates physical material flows of economic sectors and then supplements such information with environmental data in order to assess the sustainability of product groups.

The food loss and waste happening throughout the whole food supply chain, from agriculture to food consumption of households, represents a hotspot that cross-cuts products, life cycle stages, and impact categories, and thus demands specific interventions both at technological and behavioral levels.

Eco-Innovations in the Food System

Possible solutions for reducing impacts of the whole food sector or of specific product groups should strategically address the eco-innovations in the literature and in consideration of product groups, life cycle stages, and impact categories. Ideally, eco-innovations should act at different levels, such as, for example: selection of raw materials; technological improvements in manufacturing; optimization of storage, logistics, and distribution; and, consumer behavior. For each stage in the life cycle of a food system, keywords and key concepts are used to guide eco-innovation. See Fig. 1.

Initially, based on the extensive assessment conducted by [Castellani et al. \(2017a\)](#), by [Proctor \(2018\)](#), and -specifically for food processing- by [Chemat et al. \(2017\)](#), potential improvements were identified for this article through the review of existing technological eco-innovation options and existing trends towards sustainable consumption behaviors. The studies resulted in a list of areas of improvement, some of them related to specific food products, others cross-cutting among different products. The documents reviewed about eco-innovation in the food sector were scientific papers and technical reports. The eco-innovations follow.

Fig. 1 Illustration of the main concepts and principles underpinning ecoinnovation in the food system and supply chain.

Resource Extraction

Regarding the resources needed as input in the food system, two general principles are applied to enhance sustainability: Dematerialization regarding resource efficiency (doing more with less), and substitution of the most impacting resources with less impacting ones. Regarding the input in the food system, fossil resources are needed in almost all food life cycle stages but should be systematically reduced. Moreover, the food system heavily relies on mineral resources (e.g., phosphate for fertilizer production) that bring pressure on mineral resource availability. This is indicating the clear priority to be given to nutrient recovery.

Agriculture

Eco-innovation in the agricultural stage focuses on the application of green chemistry principles, nutrient efficiency, implementation of agro-ecological solutions, and resource efficiency (e.g., water and energy optimization). In agricultural activities, the hotspot of nutrients losses can be addressed both at the input stage and at the output stage. Several agronomic measures allow reducing nutrients input to crops, including the avoidance of oversupply, whereas several other technical solutions allow recovering nutrients at the end of life, e.g., from the industrial or household stage (e.g., from wastewater treatment plants). Moreover, in the post-harvest stage, several techniques are available to improve the storage of food and prevent food waste, especially for fruits and vegetables. Regarding animal-based products, the innovations aim at the optimization of feed production and the amount of feed needed per animal (e.g., improving the efficiency of feed) as well as the recovery of food waste as a source of animal feed. In general, the protection of animal welfare is also an element to be considered for the overall sustainability of meat production. Better manure management is another path to reduce emissions from manure storage and processing, e.g., by storing it on covered floors to reduce leakages or to recover it via anaerobic fermentation in order to produce biogas. Finally, animal breeding practices (especially for pigs and poultry) can reduce environmental impacts (e.g., through energy and water saving measures applied to animal housings) as well as improved nutritional strategies to reduce ammonia emissions. Concerning the hotspot of human toxicity related to metal emissions, there is the possibility to reduce the amount of metals (especially Cu and Zn) supplied to e.g. pigs through the feed.

Agro-ecological solutions are those related to a more ecological approach to agriculture, e.g., via organic or integrated agricultural practices, aiming at design and management of agroecosystems that are both productive and natural resource conserving. These solutions imply that: Crops rotate so that on-site resources can be efficiently used; chemical pesticides, synthetic fertilizers, antibiotics and other chemical compounds are reduced or banned; genetically modified organisms (GMOs) are banned or used with extreme caution; on-site resources are leveraged, such as manure for fertilizer or feed produced on the farm; and, disease-resistant plant and animal species adapted to the local environment are leveraged.

Regarding marine and aquaculture fish products, eco-innovations focus on solutions that aim at fish being sustainably caught and grown, including energy and resource efficiency and reduction of by-catch.

In the last 25 years, there has been a growth of green chemistry solutions (namely those that utilize preferably bio-based raw materials, eliminate waste, and avoid the use of toxic and/or hazardous reagents and solvents in the manufacture and application of chemical products) (Sheldon, 2017). Applying green chemistry in the food system entails the use of less hazardous chemical synthesis, safer chemicals, solvents, and auxiliaries. Thus, green chemistry affects e.g. the selection of pesticides in the agricultural phase and the use of solvents in food manufacturing.

Finally, increasing energy efficiency primarily in the form of indirect energy used for fertilizers, pesticides, and irrigation remains a crucial objective. Efficient fertilizer production technologies and avoidance of unnecessary fertilizers through adequately designed cultivation practices (e.g., precision farming) complement each other and play a major role in decreasing indirect energy inputs to agriculture. In this sense, considerable experience and data exist for organic farming no-tillage and integrated farming, which is designed to minimize energy and material inputs. An analysis of these aspects has been conducted in Europe and shows a decoupling of yield from resource inputs over time (Monforti-Ferrario *et al.*, 2015).

Food Processing and Manufacturing

“Green Food Processing” is a novel concept that aims at meeting the challenges of the 21st century and protect both the environment and consumers. Moreover, the application of lean thinking (Vlachos, 2015) is a promising way to address ecoefficiency and economic efficiency in food manufacturing. Lean thinking is a set of principles, philosophies and business processes that enable the elimination of waste and add value to customers, basically simultaneously eliminating waste (in its broader sense, everything that is not needed) and improving customer satisfaction. Notwithstanding specific energy ‘costs’ cannot be avoided, such as in chilling, freezing, or cooking, many process improvements can lead to substantial savings. In general, the most relevant solutions for the processing stage relate to the implementation of energy and water saving measures. These two factors show the highest improvement potential as identified by several Best Available Technologies Reference (BREF) documents, which for the food sector focus on food, drink and milk industries, and slaughterhouses (European Commission, Joint Research Centre, 2018).

In the study “Energy use in the EU food sector: State of play and opportunities for improvement” by Monforti-Ferrario *et al.* (2015) a detailed analysis on energy use in the European food sector was performed and areas of improvement were identified. Key processes that can be improved are cooling and freezing which in Europe accounts for about 30% of electricity consumption in the food industry. In general, the so-called “top 10 energy saving tips” in the industrial sector can be applied to the food industry. As such, possible measures span from high-efficiency motors and increased use of combined heat and power (CHP) to intelligent and

efficient lighting, or appliances' voltage optimization, all of which should be integrated into a comprehensive energy management system for a factory/industry. Moreover, the food processing industry is also exploring the possibility of recovering the energy contained in food residues on site, through biogas production or in dedicated combined heat and power plants.

Besides, most of the equipments in the food industry is sanitized (cleaned and disinfected) daily, in some cases several times per day, thus requiring the consumption of water, energy, and chemicals. For example, the European LIFE+ project "ECOD-HYBAT" demonstrated that a proper eco-design criterion can reduce the consumption of water, energy and chemical cleaning and disinfection agents in food processing companies, as well as the environmental cost of sanitation processes.

Logistics

Logistics and distribution systems, including refrigerated transport of food, can be a relevant source of impacts on resource consumption, climate change, and ozone depletion (due to refrigerants used in refrigerated transport and refrigerated storage units). A general indication is to promote the consumption of locally produced food - in their growing season- or to reduce the transportation distance. For refrigerated transport, efficient refrigeration units (e.g., switching off when not needed) can become a decisive contributing factor too. Thus, the optimization of procurement strategies plays a pivotal role in reducing food waste and improving the overall sustainability of the retail system.

Packaging

The reduction of packaging mass per unit of product has been a well-known key factor for reducing the environmental impacts. Recently, the issue of increasing the use of easy-to-recycle and bio-based materials has become a hotspot. However, alternatives should be carefully assessed because of possible trade-offs between the potentially increased environmental impact of packaging and the need for reducing food waste.

Consumption Phase

Eco-innovations in the use phase are mainly related to consumer choice and behavior. For example, since meat and dairy products production chains have higher environmental impacts, several studies model the possible environmental impact reduction through dietary shifts (e.g., comparing the environmental impact of different dietary protein choices). Besides, the consumption of ready-made products has been globally increasing. The preparation of ready-made meals and ready-made products (such as fresh-cut vegetables) is an activity that produces additional impacts if compared to less-processed food. Therefore, the reduced consumption of ready-made products can bring environmental benefits. However, impacts associated with meals prepared at home also exist, and due to the efficiency of mass production, a ready-made meal can be (or can become through technological improvements) more sustainable. Several improvements are proposed for catering services, especially in regards to sustainability strategies in the purchase of food, the type of cooking option, the selection of cutlery and dishes (e.g. avoiding single-use items).

End of Life and Food Waste

Food loss and waste are increasing worldwide due to a number of different production and consumption drivers. The increasing food demand provides new market opportunities in the agro-farming sector, such as the reduction of impacts and the maximization of resource recovery. Solutions to food waste are numerous and include waste prevention strategies, industrial symbiosis at the processing stage (Mirabella *et al.*, 2014), recovery of waste at the end of life (e.g., to produce animal feed), and avoiding the landfilling of organic waste. Assessing food systems with LCA includes assessment of the end of life phase, namely the food waste generated in the different life cycle stages, and the potential for resource efficiency regarding recovery of materials and energy from food waste. The identification of eco-innovations related to food waste requires several steps: (i) The systematic accounting of food loss generated along the stages of the food supply chain; (ii) the modeling of waste treatments according to the specific characteristics of food, and (iii) the modeling of multi-functionality. Corrado *et al.* (2017) proposed an approach with the goal to improve food waste modeling. Moreover, the use of unavoidable food waste or food by-products as input for added value bio-based materials to be used in pharmaceuticals, nutraceutical (Mirabella *et al.*, 2014), becomes a source for reducing impacts and promoting a circular bioeconomy.

Eco-Innovation Analysis With LCA

Identification of eco-innovations is not enough, as there is a need of verifying the magnitude of the benefits and the existence of possible trade-offs. This benefit analysis is needed to: Avoid that an expected benefit in an impact category poses a burden on another category; avoid that reducing impact in a life cycle stage implies additional burden in another stage; and, validate that the innovation leads to an overall benefit. The assessment of potential benefits in LCA results from the analysis of a baseline scenario and its contrast against additional scenarios representative of all life cycle stages and factor variances. This analysis is often complemented with optimization functions, namely prioritization of interventions based on benefit maximization (e.g., an environmental and economic optimization of food prevention actions, see by Cristobal *et al.*, 2018).

Conclusion

Eco-innovations are pivotal towards more sustainable food supply chains and entail technological, organizational, and behavioral aspects. Eco-innovation analyses should focus on the identification of critical impact hotspots and should be assessed with holistic LCA approaches that encompass all the life cycle stages from the extraction of raw materials to the end of life. The assessment of potential benefits in LCA results from the analysis of a baseline scenario and its contrast against additional scenarios representative of all life cycle stages and factor variances. This article presented an overview of possible areas of eco-innovations with a life cycle perspective. Core eco-innovations were identified in resource extraction, agriculture, processing and manufacturing, logistics, packaging, consumption, and end of life. The complexity of the challenges in the food system requires enhancing the cross-pollination among difference science domains (such as environmental, technological, social, and economic ones) that are required to support the definition and the implementation of eco-innovations. The implementation of an eco-innovation requires the life cycle modeling in order to validate its potential benefits, to assess the magnitude of such benefits, and to unveil possible trade-offs.

Edible Films and Coatings for Fruits and Vegetables

Sanjib K Paul, Biotechnology and Allied Science Group, IPO, Kolkata, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Fruits, vegetables and other food products are preserved or stored since the beginning of human civilization. With technological developments the way of storage and preservation of food products including fresh fruits and vegetables also changed and modernized. The techniques such as chemical fungicides, modified atmosphere packaging (MAP), controlled atmosphere packaging/storage (CAP/CAS) and plastic films are being used for post-harvest management of fruits and vegetables since many decades (Mario *et al.*, 2010). Though these technologies are dominating the sector of post harvest management and storage of fruits and vegetables but still they produce lots of limitations like- growth of tolerant pathogens, fungicide residual hazards, anaerobiosis, improper ripening and off-flavor development but failed to increase the shelf life up to maximum desirable level. Further, these techniques are not universally applicable for all perishable fruits and vegetables. So, an urgent need of an alternative technique such as edible coating with active functional materials like – antioxidants and antimicrobials etc., was realized to inhibit the rapid quality degradation of food products including horticultural crops without significant risk to environment and health hazards.

Application of edible films and coatings in food products including fresh fruits and vegetables seems new, but its basic technology is an age-old practice. Wax coatings have been applied to reduce dehydration of citrus fruits in China since 12th centuries (Guilbert and Biquet, 1986). Use of coating in meats to thwart shrinkage has been in practice since at least 16th century, where meat cuts were coated with lipids (Kester and Fennema, 1986a,b). Yuba, which is a proteic edible film obtained from the skin of boiled soybean milk, was conventionally used in Asia to enhance the exterior and preservation of various food products since the 15th century (Gennadios *et al.*, 1993). Later in the last century, the preservation of meat and other perishable food products by coating them with gelatin was recommended (Contreras-Medellin and Labuza, 1981). In the 19th century, sucrose was initially applied as an edible coating on dry fruits and nuts to prevent oxidative rancidity during storage. The more important application of edible films and coatings extensively started particularly since the 1930s with the use of an emulsion made of waxes spread on fruits to improve their appearance (shininess, color, softening), onset of mealiness, carriage of fungicides, and to better control their ripening and to delay the dehydration. Over the last 40 years, extensive researches on the optimization of formulation, methods of application, and characterization of edible films and coatings have been carried out and reported in both scientific and patent literature.

Many types of material used for enrobing (i.e., wrapping or coating) various food to extend shelf life of the product that may be eaten together with the coated food. Both edible films and coatings are similar in composition but basic difference among them is edible coating remain adhered with the surface of the product, whereas edible films do not adhere with the product rather it fulfills the utility of wrapping or packaging purposes. Edible coatings and films are generally produced from renewable natural and biodegradable polymeric materials such as polysaccharides, proteins, lipids, or the combination of these components (composite and conglomerate coating/film). For the past decade, research on edible films and coatings in foods is driven due to the high demand of consumers for longer shelf-life and better quality of fresh foods as well as of environmentally and health friendly packaging (Debeaufort *et al.*, 1998; Tharanathan, 2003; Cha and Chinnan, 2004; Siracusa *et al.*, 2008).

It is being observed that coatings and films with single basic material possess several limitations. To overcome the drawbacks of single component edible films and coatings, a concept of combining the unique features of different individual coating materials in desired combination has been developed in the name of composite coatings and films. It is constructed either by making successive layers of different film forming material, or in the form of a single layer film from emulsion, suspension or dispersion in the immiscible layers at a time, or by making solution of different materials in the same solvent and subsequent formation of film or coating. In this direction, edible coatings made with chitosan and yam starch demonstrated significant antimicrobial activity when used in the coating of carrots (Durango *et al.*, 2006), strawberries (Mali and Grossmann, 2003), mango etc (Vargas *et al.*, 2006) and raspberries, as well as in table grapes inoculated with *B. cinerea* (Romanazzi *et al.*, 2002).

Further, functional and active edible coatings and films are also being developed by introducing certain materials like- antioxidant, antimicrobial and nutraceuticals into the coating or film which prevents the growth of micro organisms, reduce oxidative degradation and also enhance the nutritive value of the packaged food (Bifani *et al.*, 2006; Lin and Zhao, 2007; Vargas *et al.*, 2008). Reported that different functional materials including nanomaterials in edible coatings can increase the desired functionalities of packaging materials extending the shelf life of the coated produce. The extract of natural herbs can also be incorporated inside the molecular orientation of the edible polymeric base of edible coatings and films (Paul, 2018). Edible films and coatings with tea extracts, different edible oils etc are already applied successfully to extend the shelf life and retention of quality attributes. In edible films and coatings these additives demonstrated prolonged and controlled efficacy due to their immobilization inside the polymeric chains. These extracts are also eliminate the application of hazardous chemical substances and are expected to contribute positively in the search of green and natural materials.

In addition to the natural extracts, various active, smart and intelligent functional additives are also being incorporated into edible films and coatings to achieve certain goals. It is demonstrated by various researchers that appropriate incorporation of

certain engineered substances including nanomaterials in edible films and coatings substantially enhance the required functionalities of the film or coating by controlling microbial, enzymatic, biochemical reactions of the internal environment. Their incorporation can also impart in low oxygen availability, controlled release of carbon dioxide and excellent mechanical and barrier properties. Though in present days, scientists are interestingly creating a domain for novel application of nanotechnology in various fields of food processing keeping in mind about their probable risks and safety issues, but till now very little research has been done in the area of edible nano-packaging for foods especially fruits and vegetables. Observing and analyzing each and every dimension of developments of edible films and coatings author expects that improved edible films and coatings with various active materials including natural extracts, their nanomaterials and safer synthetic nanomaterials will dominate among the existing technologies for preservation and primary packaging of fruits, vegetables and various other food products.

Edible Films and Coatings

Any type of material used for enrobing (i.e., wrapping or coating) various food to extend shelf life of the product and/or value addition that may be eaten together with food with or without further removal is considered as edible film or coating. Both edible film and coatings are similar in composition but basic difference among them is edible coating remain adhered with the surface of the product, whereas edible film do not adhere with the product rather it fulfills the utility of wrapping or packaging purposes. Edible films and coatings have been applied on meat, poultry, seafood, fruits, vegetables, grains, candies, heterogeneous and complex foods, or fresh, cured, freeze, and processed foods. An ideal coating is defined as one that can extend storage life of fresh fruits or vegetables without causing anaerobiosis and reduces decay without affecting the quality of the coated fruits or vegetables (Ghaouth *et al.*, 1992). When edible coating or film contains any functional or active material (antioxidant, antimicrobial or nutrients etc.) then it is termed as functional edible coating or film, which seems to have tremendous scope for value addition and storage. Improvement of the technology in this domain is of great importance for the present day food and packaging scientists. For the past 10 years, research on edible coatings in foods is driven due to the high demand of consumers for longer shelf-life and better quality of fresh foods as well as of environmentally and health friendly packaging (Debeaufort *et al.*, 1998; Tharanathan, 2003; Cha and Chinnan, 2004; Siracusa *et al.*, 2008). Indeed, edible coatings can be used as a vehicle for incorporating natural or chemical antimicrobial agents, antioxidants, enzymes or functional ingredients such as probiotics, minerals and vitamins (Bifani *et al.*, 2006; Lin and Zhao, 2007; Vargas *et al.*, 2008).

Edible coatings provide replacement and/or fortification of natural layers to prevent moisture losses, while selectively allowing for controlled exchange of important gases, such as oxygen, carbon dioxide, and ethylene, which are involved in normal respiration processes and ripening of fruits and vegetables. A coating can also provide surface sterility and prevent loss of other important components.

The principal reason of fruit and vegetable spoilage are gas exchanges (respiration and transpiration) during ripening and storage, and/or microbial growth, particularly molds and rots. In addition, changes in gas transition leads to various other equally important detrimental characteristics. These include loss or change of flavor and aroma, esthetically unacceptable appearance and changes in texture (Paul, 2018).

The main advantage of edible coatings over traditional synthetics is that they can be consumed with the products and are environmentally safe. The coatings are produced exclusively from renewable and edible ingredients and therefore are anticipated to degrade more readily than polymeric materials. Edible coatings can enhance the organoleptic properties of coated foods provided they contain various components (flavorings, colorings, sweeteners). Their use based on natural polymers and food grade additives has been constantly increasing in the food industries, including fruits and vegetables. The coatings/films can be produced with a variety of natural products such as polysaccharides, proteins and lipids, with the addition of plasticizers and surfactants. The functionality and performance of edible coatings mainly depend on their barrier, mechanical and optical properties, which in turn depend on coatings composition and manufacturing process. The choice of an edible coating mainly depends on the specific characteristics of the food product that requires protection and its storage conditions.

The new generation of edible coating is being especially designed to increase their functionalities by incorporating natural or chemical antimicrobial agents, antioxidants, enzymes or functional ingredients such as probiotics, minerals and vitamins (Bifani *et al.*, 2006; Vargas *et al.*, 2008). Antimicrobial and antioxidant coatings have advantages over direct applications of the antimicrobial or antioxidant agents because they can be designed to slow down the diffusion of the active compounds from the surface of the coating. Edible coating can enhance the nutritional value of foods by carrying basic nutrients and/or nutraceuticals in its matrix. The sensory quality of coated products can be also improved if flavor and pigment compounds are added in the matrix. Incorporation of antimicrobial agents such as benzoic acid, sorbic acid, propionic acid, lactic acid, nisin, and lysozyme in coating have shown retarded surface growth of bacteria, yeasts, and molds on a wide range of products, including various fruits and vegetables. Various antimicrobial edible films have been developed to minimize growth of spoilage and pathogenic microorganisms. The effect of coatings on fruits and vegetables depends greatly on temperature, alkalinity, thickness and type of coating, and the variety as well as maturity/ripening stage of the fruits and vegetables (Park *et al.*, 1994). Various types of polysaccharide-based (cellulose, chitosan, alginate, starch, pectin, and dextrin), protein-based (wheat gluten, collagen, corn zein, soy, casein, and whey protein), lipid-based (waxes, acylglycerols, and fatty acids) edible films, as well as their composites are already developed and at present these are a commercial reality. Wide ranges of functional agents are being successfully incorporated into such

coatings during manufacture and several are yet to explore to enhance the safety and shelf life of fresh and ready-to-eat foods including fruits and vegetables.

Edible Coating Materials

Hydrocolloids (i.e., Proteins and Carbohydrates) and Lipids are the base matrix materials that generally being used for the production of edible films and coatings. Combinations of different materials at various ratio in the form of composite films or coatings are the improved type with higher functionality to address the limitations of the individual one (Li and Barth, 1998; Park *et al.*, 1994; Guilbert *et al.*, 1996a,b; Mahmoud and Savello, 1992).

Hydrocolloid materials

Hydrocolloids are hydrophilic polymers that generally contain many hydroxyl (-OH) groups. Now-a-days they are widely used as the base material for film-forming solution to execute and control the texture, flavor, color and shelf-life of foods (Williams and Phillips, 2000). They are fully or partially soluble in water and are used principally to increase the viscosity with or without the external application of heat to the continuous phase of the film forming solution i.e., as gelling agent or thickener (Baldwin *et al.*, 1995; Kester and Fennema, 1986a,b). They also possess the stabilization property to prevent the separation of emulsion (if the coating or film contains oil-in-water or water-in-oil components) due to an increase in viscosity of the aqueous phase. The kinetic motion of the oil droplets is reduced, resulting in a lower rate of flocculation and coalescence in the film.

Polysaccharide based films and coatings

Polysaccharide films and coatings are principally made from starch, pectin, cellulose (Li and Barth, 1998), chitosan (Zhang and Quantick, 1998, 1997; Ghaouth *et al.*, 1991, 1992; Jiang and Li, 2001; Cheah *et al.*, 1997; Li and Yu, 2000) and alginate etc. Due to their ability to form gel, thickening quality, viscosity and adhesiveness during the application of coating, as well as their efficacy to impart hardness, crispiness and compactness to the final product, they are extensively utilized in the practical field. Because of the makeup of the polymer chains, these coatings exhibit excellent gas permeability properties, resulting in desired modified atmospheres that enhance the shelf-life of the product, especially fresh products like – fruits and vegetables, without creating anaerobic conditions (Baldwin *et al.*, 1995). Additionally, polysaccharide films and coatings can be used to extend the shelf-life of various foods by preventing dehydration, controlling oil and aroma transmission, oxidative rancidity and surface browning but their hydrophilic nature makes them poor barriers for water vapor. The primary advantages of polysaccharide films or coatings are their structural stability and ability to slow down oxygen transmission due to their tightly packed, ordered hydrogen bonded network and low solubility. As a general rule coatings or films which do not provide protection against water transmission often have desirable properties in preventing oxygen transmission and vice versa (Banker, 1966). These coatings may retard ripening and increase shelf life of coated fruits and vegetables, especially climacteric fruits without creating severe anaerobiosis (Arvanitoyannis and Gorris, 1999).

Protein based films and coatings

Corn zein, wheat gluten, milk proteins, whey proteins, soy proteins and gelatin are being extensively studied for their film and coating forming ability, their features and functional efficacy in terms of quality retention and shelf life of coated products. Protein based films and coatings exhibit better resistance to gas transmission and mechanical and structural properties than polysaccharides. As like polysaccharide films, protein based films also possess excellent oxygen, aroma, and oil barrier properties. But, it also shows poor water vapor barrier property due to their hydrophilic nature (Baldwin and Baker, 2002). Like other films and coatings, properties of protein based films and coatings also directly depend upon type, composition and application/formation process of the coating and/or film (Sothornvit and Krochta, 2000, 2001; Sothornvit *et al.*, 2002; Cho and Rhee, 2002; Wan *et al.*, 2005).

Lipid based films and coatings

Lipid substances are utilized as protective coating to improve the gloss and most importantly to prevent moisture transmission, due to its hydrophobicity. Moisture transmission rate decreases with the increase in hydrophobic phase. Lipids offer limited oxygen barrier properties due to the presence of microscopic pores and elevated solubility and diffusivity. Lipid films or coatings are usually opaque, lack structural rigidity, mechanical strength and relatively inflexible (Guilbert *et al.*, 1996a,b). Due to their low polarity, films from lipid become thicker and brittle and thus they must be combined with different film forming hydrocolloids or their derivatives to provide mechanical and structural strength (Debeaufort *et al.*, 1993). Several lipid materials including paraffin wax, bee wax, acetoglyceride, shellac resins etc are extensively used to provide edible surface coating to retain the quality attributes of various fruits, vegetables and other food products during storage (Figs. 1 and 2).

Composite films

To overcome the drawbacks of single component edible films and coatings, a concept of combining the unique features of different individual coating materials in desired combination has been developed in the name of composite coating. It is constructed either by making successive layers of different film forming material, or in the form of emulsion, suspension or

Fig. 1 Classification of edible films and coatings based on generally used material.

dispersion in the immiscible layers at a time, or by making solution of different materials in the same solvent and subsequent film or coating application. Improvement of mechanical, structural and permeation properties of the film or coating is the main motto of producing composite films. Extensive work has been carried out by the researchers exploring various improved properties by combining different proportions of methyl cellulose and fatty acid (Kamper and Fennema, 1984), lipid and hydroxypropyl methyl cellulose (Hagenmaier and Shaw, 1990), methyl cellulose and lipid (Greener and Fennema, 1989), methyl cellulose and fatty acid (Sapru and Labuza, 1994), casein and lipids (Avena-Bustillos and Krochta, 1993), gelatin and soluble starch, hydroxypropyl starch and gelatin (Arvanitoyannis *et al.*, 1998), corn zein and corn starch (Ryu *et al.*, 2002), gelatin and fatty acid (Bertana *et al.*, 2005), soy protein isolate and polylactic acid (Rhim *et al.*, 2007) to maximize the quality retention and extension of shelf-life of the coated items.

Methods for Film and Coatings Formation

Formation and/or processing techniques differ between edible film and coating. Edible coatings are mostly applied on the surface of the material by dipping, brushing and spraying of the coating solution depending upon the feasibility, whereas, like thermoplastic polymeric structures solvent casting, extrusion, spinning etc. are the mostly used techniques of present day for edible film formation and processing. In food industry, coating by spraying is the conventional method generally used when the coating forming solution is not very viscous. Indeed, highly viscous solution cannot be or very easily sprayed and brushing also can't coat a material in a homogeneous and uniform way. Thus only dipping techniques can be applied giving high thickness to the coating with uniformity. The adhesiveness of the coating on the surface of the food product mainly depends on its specific nature, i.e., on its affinity, but little depends on the coating technique used. Affinity depends on the physical nature and on the number of interactions or bondings between coating and support surface. So, the use of substances like-emulsifiers makes possible the sticking of a hydrophobic coating on a hydrophilic food surface (Gontard and Guilbert, 1994). On the other hand, coating thickness depends essentially on the application technique and on the viscosity of the formulation (Fellows, 1990).

Formation of effective and quality edible coating requires several sophisticated steps and optimized judgment. The basic process of present day as standardized by this author (Paul, 2018) for the development of a new edible coating on a product is explained in the following outline:

- (1) Preparation of coating formulations by taking a range of independent variables and varying their concentration in the formulation.
- (2) Designing of experiments by using appropriate statistical method like- Central Composite Rotatable Design (CCRD), Completely Randomised Block Design (CRBD) based on number of variables and set of run.

Fig. 2 General flow diagram of application/production of edible coating and film.

- (3) Model fitting and soft computing optimization of the composition of coating formulation among the set of formulations based on the experimental results of coating attributes and product characteristics.
- (4) Impregnation of additives at a range of concentration into the optimum coating formulation (if desired).
- (5) Application of coating by modern coater (may be separately developed and optimized based on the product type) at standardised thickness throughout the process.
- (6) Storage analysis of the coated product and determination of minimum but most effective concentration of additives by statistical tools in terms of retention of quality attributes and extension of shelf life.
- (7) Compilation and recommendation of final process and formulation by model validation with experimental data.

Now a day's dipping is a common method for applying coatings on fruits and vegetables (Vargas *et al.*, 2008). The coating is made by dipping in a coating solution with standardized properties such as density, viscosity and surface tension, as well as keeping time and food withdrawal speed from the coating solution (Cisneros-Zevallos and Krochta, 2003). These properties have direct effect on the final coating thickness and thus different theoretical approaches can be used to estimate film thickness from coating solution properties (Snoeijer *et al.*, 2008). Generally the food is dipped into the film-forming solutions between 5 and 30 s and suitable coatings are obtained with remarkable utility (Vargas *et al.*, 2006; Ayranci and Tunç, 1997). Direct application of antimicrobial agents onto food surfaces by dipping has proven to be less effective as there is loss of activity because of leaching onto the food, enzymatic activity, and reaction with other food components and therefore embedding the active materials into

coating base can show higher efficacy limiting the problems. The application of edible coating to minimally processed fruits is not easy because it is difficult to obtain a good adhesion of the coating to the hydrophilic surface of the cut fruit. A solution to solve this problem could be a multilayer composite technique: the layer-by-layer electro deposition where two or more layers of material with nanometer dimensions are physically or chemically bonded to each other (Vargas *et al.*, 2008; Weiss *et al.*, 2006).

In case of edible film production, the process up to the preparation of coating or film forming solution/gel/colloid is same like the process of edible coating (till step (iv) of the outline) as described in previous paragraph. Appropriate film forming method should be selected depending upon the properties of base material, prepared formulation, product to be packaged and requirement of any special features in the produced film. Techniques used for the producing of flexible plastic films can also be used for edible and biodegradable films (Lindstrom *et al.*, 1992; Fellows, 1990). These techniques can be extrusion or co-extrusion for multilayer films, solvent casting, spinning, lamination, and roll-drying for the solvent removal of the polymer formulation. After the film processing it should be dried carefully and produced films are used for packaging purposes.

Properties of Edible Films and Coatings

Thickness

Thickness of edible films and coatings is an important parameter since it directly affects the biological properties and shelf life of the coated food by interfering permeability, transparency etc. The effectiveness of edible films and coatings for protection of food depends primarily on controlling the spreading of the coating solutions, which affect the thickness of the film and thus leading to its affect into porosity, transparency, gas and water vapor permeability etc.

Mechanical properties

Tensile strength, Young's modulus and elongation at break are the most important key parameters to study the mechanical properties of edible film, whereas for edible coating these properties are not directly determined. Still, these properties are indirectly associated with various other properties of edible coating that significantly affect the product quality. Researchers have determined these parameters from the stress-strain curves according to the norm of the American Society for Testing and Materials (ASTM). These properties of films are very important for their application as a packaging material. These properties indicate the strength, elasticity and protect-ability of the film.

Barrier properties

Protecting features of edible films or coatings against the permeation of gases, water vapor, oil, aroma compounds and light are very important key factors for maintaining the quality of the products during storage and extension of the shelf-life, which determine the efficacy of the film or coating. Chemical composition and structure of the film/coating-forming polymers, composition of film/coating solution, interactions between the sorbent and solvent, processing and drying parameters, the characteristics of the product, and the storage conditions are mainly responsible for the barrier properties of the film or coating (Paul *et al.*, 2015, 2018; Paul, 2018).

Optical properties

Optical properties are characteristics of surfaces which are detected by human vision affecting some crucial aspects including esthetic properties of food quality. Gloss, transparency and color are the main optical properties of edible coatings and films. The internal and surface film microstructure together plays an important role in overall optical properties of the film and coated product. Indeed, the intensity of light reflected by the coated food is determined both by the light directly reflected at the interface between air and the coated food surface, which is responsible for the gloss of the product (specular reflection) and by both the light re-emitted out of the surface in all directions after penetrating into the coating of the food and scattering internally (indirect reflection) depending upon the transparency of the coating. Specular reflection is related to the gloss of the coating or film. The gloss and indirectly specular reflection property of edible coatings as well as film is affected by coating microstructure in particular, by the type and level of surfactant, the distribution and the size, particle diameter of dispersed phase, relative humidity, storage time and the surface roughness (Nikolova *et al.*, 2005; Villalobos *et al.*, 2005). The transparency of films was measured through the surface reflectance spectra in a spectrophotometer, which is inversely proportional to the absorbance at a particular wavelength (Das *et al.*, 2013; Paul *et al.*, 2015).

Thermodynamic parameters associated to sorption phenomenon

The interactions of between the sorbant and solvent can define the efficiency of the edible film and coating to control the gas permeability and therefore also controls the respiration and ripening of fresh fruits and vegetables, as well as the stability of the coated food. The relationship between the total moisture content and the water activity (A_w), over a range of values, at constant temperature, yields the sorption isotherm when expressed graphically. When obtained at different temperatures, the energy associated to moisture interactions at low water vapor pressures can be estimated. Various mathematical models have been developed to describe sorption isotherms, which are also used to standardize the edible films and coatings to achieve better efficacy (Sabeti *et al.*, 2015).

Advantages of Edible Films and Coatings

Edible coatings and films are used to improve food appearance and conservation due to their various advantages over usual synthetic packaging materials. These are produced from both animal and agricultural products, hence possess environment-friendly, biodegradable and eatable nature. Edible packaging also reduces the wastage of packaging materials in compared to synthetic packaging (Petersen, *et al.*, 1999; Park *et al.*, 1994; Sothornvit and Krochta, 2000). They act as barriers to moisture, oxygen and other gases during processing, handling, and storage (Li and Barth, 1998; Avena-Bustillos *et al.*, 1994a,b), and not only retard food deterioration but also enhance its safety due to either their natural biocidal activity or the incorporation of antimicrobial compounds, that also leads to the advancement of the concept of active packaging (Appendini and Hotchkiss, 2002; Cha and Chinnan, 2004). Thus, the use of an edible coatings and films, such as chitosan and yam starch were found to be a viable alternative for controlling microbial growth in minimally processed carrots (Durango *et al.*, 2006), strawberries (Mali and Grossmann, 2003), and raspberries (Han *et al.*, 2004), as well as in table grapes inoculated with *B. cinerea* (Romanazzi *et al.*, 2002).

Advantages of edible films and coatings also include, improved retention of moisture, firmness, color, acids, sugars, and flavor components, reduced weight loss, reduction of storage decay, improved consumer appeal and extended shelf-life (Park *et al.*, 1994; Sothornvit and Krochta, 2000; Davis and Hofmann, 1973; Avena-Bustillos *et al.*, 1994a,b, 1997; Baldwin *et al.*, 1995).

Edible films and coatings have also found to retard respiration rates (Banks, 1984), reduce ethylene production (Banks, 1984; Baldwin *et al.*, 1995), reduce metabolism and oxidation rates (Li and Barth, 1998), hinder solute movement (Li and Barth, 1998), retard loss of chlorophyll and other coloring compounds thus retaining the color (Banks, 1984), seal in flavor volatiles, carry additives that could contribute in their specific functionality (Baldwin *et al.*, 1995).

Thus the major benefits of edible films and coating are that they can be consumed along with food, can provide additional nutrients, may enhance sensory characteristics and may include quality enhancing antimicrobials and antioxidants and also extension of shelf-life as well as preservation of product quality during storage (Guilbert *et al.*, 1996a,b).

Limitations and Ongoing Improvement Strategies

Even though some edible coatings and films have been successfully applied to fresh produce and substantial scopes are seen to address several technological problems but some correctable limitations are also observed which may further reduce limitations in terms of quality aspects of the product and food safety. Modification of internal atmospheres by the use of edible coatings can increase disorders associated with high carbon dioxide or low oxygen concentration leading to anaerobiosis (Smith *et al.*, 1987). It was observed that tomatoes coated with 5–66 μm zein film produced alcohol and off-flavors internally which were attributable to an internal gas composition with too low in oxygen and too high in carbon dioxide (Park *et al.*, 1994). It was also found the development of alcoholic flavors in apple and pear due to inhibition of normal respiration rate leading to anaerobic fermentation on sufficient wax coating. Increased core flush incidence was also observed along with some other different advantages in apple when coated with sucrose fatty acid ester (Momen *et al.*, 1997). Sometimes, micro organisms can also get favorable condition for their growth in edible coating or film that may leads to the mass scale spoilage of the product. Another existing disadvantage of these techniques is the loss of quality of the edible coatings and films since there is no control over the shape, size and size distribution of the dispersed elements (e.g., additives, ingredients, etc.) in the support structure matrix. Another disadvantage of these techniques is that the thickness of the films is generally not constant and difficult to control.

To overcome these problems so many strategies are being adopted and some can still be adopted after thorough research in the aspect of analysis, value improvement and optimization. The effects of edible coatings on internal gas composition and their interactions on quality parameters must be determined for coated fresh produce. For example, color change, rate of ripening, firmness, ethanol fermentation, decay-ratio, and weight loss are very important quality parameters of fruits and vegetable in terms of storage and shelf life (Ninja *et al.*, 2017; Paul, 2018). Also, if a coating is too thick, detrimental effects can result due to an internal oxygen concentration below a desirable level and an associated increased carbon dioxide concentration above a critical tolerable level. Such a condition leads to anaerobic fermentation and off flavor formation. In this regard, it is proposed that these issues can be addressed by: (a) developing several edible coatings with suitable structural additives like- plasticizer with different concentrations and combinations and optimizing the independent parameters with respect to the dependant, (b) incorporation of functional materials like antimicrobial, antioxidants (e.g., natural, permitted chemicals or suitable nano materials etc.) in different concentration into the optimized concentration and analyzing its effects after coating, (c) measuring volatile components and gas permeation properties of selected coatings, (c) measuring diffusion properties of skin and flesh of selected fruits, (d) predicting internal gas compositions for the fruits coated with edible films with respect to the coating period, and (e) observing coating effects on the quality changes of the coated products with respect to the coating period.

Functional Additives and Other Strategies to Improve Edible Films and Coatings

Improvement of mechanical and functional properties of edible films and coatings is done by adding certain additional substances like – plasticizer, oils, natural active materials, antioxidants, antimicrobials, nutrients, colorants, vitamins, probiotics etc., into the coating solution, which may be termed as additives. However, plasticizers are the main and commonly essential additives used in films and coatings. Antioxidant and antimicrobial agents can play remarkable role in extension of shelf life by preventing oxidation by limiting oxygen availability and microbial degradation respectively. Other functional additives may have

preservative, nutritional or esthetic value to the coated product. Various natural functional extracts and phytochemicals as well as green nanomaterials with tremendous functionalities have become the most important zone of interest among the global scientists to combine them with edible coatings and films. These materials have no or very minimum hazards to environment and may also add some nutritional and nutraceutical benefits to the consumers. The ability of edible films to retard moisture, oxygen, aroma and solute transport may be improved by introducing additives such as antioxidants, antimicrobials, colorants, flavors, fortifying nutrients and spices in film formulation (Pranoto *et al.*, 2005).

Plasticizers

These are small molecular-weight compounds that can be added mainly in an edible film or coating solution to improve the flexibility and mechanical properties of the film matrix. As a general rule, the addition of a plasticizer increases the permeability of a film or coating. Plasticizer combines with the main component of the film, moving the component's chains apart, and thus reduces rigidity of the structure (Guilbert and Biquet, 1996). Without plasticizers, most films and coatings are brittle, and it is difficult to form a homogenous film. The effectiveness of a plasticizer depends upon three things: size, shape and compatibility with the matrix (Sothornvit and Krochta, 2001). Plasticizer also attracts water molecules around it, which reduces intermolecular interactions of the main component (Ke and Sun, 2001). Plasticizers normally generate a homogenous mixture without phase-separation. There are two types of plasticization: internal and external. Internal plasticizers chemically modify a polymer chain through addition of substituent groups attached via covalent bonds. Internal plasticizers create steric hindrance between the polymer chains, leading to increased free volume and improved flexibility. External plasticizers solvate and lubricate the polymer chains, lowering the glass transition temperature of the base polymer and also increasing the free volume. The most effective plasticizer is, of course, water. The state of the plasticizer under normal storage conditions may also affect its permeability and flexibility. Solid plasticizers may have an "anti-plasticizing" effect, and decrease matrix flexibility, while improving permeability (Dangaran and Krochta, 2007). In traditional polymer-plasticizer systems, anti-plasticization occurs when a plasticized system is harder and less flexible than the pure polymer at a temperature below the glass transition or T_g (Chang *et al.*, 2000; Morara *et al.*, 2002).

The most commonly used plasticizers for polysaccharide films are glycerol, sorbitol and polyethylene glycol (Sothornvit and Krochta, 2005; Mali and Grossmann, 2003). Disaccharides such as sucrose and monosaccharides (e.g., fructose, glucose, and mannose) have been investigated as their potentiality as plasticizer and found to be exhibiting films with lower WVP compared to those containing polyols as plasticizers (Zhang and Han, 2006; Olivas and Barbosa-Cánovas, 2008). Fatty acids have also been used as plasticizers in edible films and coatings, though they are not very common. A mixture of starch and alginate to form edible film has been studied to improve the mechanical properties of film. The mesquite gum forms films with excellent water vapor barrier properties when small amounts of lipids are added in their formulation. Addition of plasticizer such as glycerin in gluten films is very useful to improve film flexibility (Gennadios *et al.*, 1994). However, increasing film flexibility by increasing sorbitol content reduces film strength, elasticity and water vapor barrier properties (Contard *et al.*, 1993). Tensile strength of gluten films can be improved by using a cross-linking agent such as glutaraldehyde, or heat curing at 80°C (Gennadios and Weller, 1992; Koelsch and Labuza, 1992).

Antimicrobial and antioxidant agents

Antimicrobial and antioxidant coatings have advantages over their direct applications because they can be designed to slow down the diffusion of the active compounds from the surface of the coated food. The use of active or functional edible films and coatings in food protection and preservation has recently increased since they offer several advantages over synthetic materials, such as being biodegradable and eco-friendly (Tharanathan, 2003; Ponce *et al.*, 2008).

Antimicrobial agents: The antimicrobial coatings and films are rapidly developing technologies that are being employed for controlling the microbiological decay of perishable food products (Del Nobile *et al.*, 2008). Common chemical antimicrobial agents used in food systems, such as benzoic acid, propionic acid, sodium benzoate, sorbic acid, and potassium sorbate etc may be incorporated into edible films and coatings to inhibit the outgrowth of both bacterial and fungal cells. In fact, the antimicrobial compounds, when establish contact with food, inhibit the growth of microorganisms present in the surface (Appendini and Hotchkiss, 2002). These films could prolong the shelf-life and ensure the safety of foods by acting as a hindrance for growth of pathogenic and spoilage microorganisms due to their lag-phase extension and/or their growth rate reduction. However, due to the health concerns of consumers related to chemical preservatives, the demand for natural substances has spurred the search for natural bio-preservatives in edible films-forming preparations. The most frequently used bio-preservatives as antimicrobial are lysozyme and nisin. These biopreservatives are shown bactericidal effect on Gram (+ve) bacteria but they can also become effective on Gram (-ve) bacteria if they are combined with chelating agents such as ethylene diamine tetraacetic acid (EDTA). Common other bio-preservatives that may be used in edible films and coatings are other bacteriocins, such as lactacin and pediocin and antimicrobial enzymes, such as chitinase and glucose oxidase. Natural antimicrobial compounds have also been incorporated into protein or polysaccharide-based matrices: rosemary, and garlic essential oils, lemon grass, cinnamon oil etc at different concentrations.

Antioxidants: Incorporation of antioxidants in edible films-forming preparations to increase product shelf life by protecting foods against oxidative rancidity, degradation, and discoloration has become very popular. Most antimicrobial compounds also have antioxidant properties. Natural antioxidants such as phenolic compounds (such as carvacrol, camphor, eugenol, linalool and thymol), vitamins E and C in place of synthetic antioxidants are extensively used in edible films. Essential oils and various extracts exhibit a wide range of biological effects, including antioxidant and antimicrobial properties.

Essential oils

Consumers have been continuously moving towards the food products with NO or LESS chemicals. So, the searches for natural substances which can act as alternative active and functional materials are in peak. Essential oils are one of the search outputs those are aromatic, natural antioxidant, and antimicrobials obtained from plant sources. They consist of a mixture of various natural functional compounds, such as terpenoids, phenolic acids, terpenes, and various other aromatic and aliphatic compounds, but their exact composition varies based on their source. The presence of essential oils can extend the shelf life of food products by limiting microbial growth and preventing lipid oxidation (Tongnuanchan *et al.*, 2013; Perdonés *et al.*, 2014).

However, some of their properties like- strong aroma, risk of toxic effect, and alteration of organoleptic properties of the food – have restricted their application in direct food preservation. However, a strategy is being developed to solve this problem by incorporating essential oils into edible films and coatings. It is possible to reduce the required doses by immobilizing them into the polymeric matrix, which limits their volatilization, controls their leaching, and preserves the quality and maintain the safety of fresh and fresh-cut fruits and vegetables (Sánchez-gonzález *et al.*, 2011; Bonilla *et al.*, 2013; Ruiz-Navajas *et al.*, 2013).

Tongnuanchan *et al.* (2013) studied the antioxidant properties of the edible film made by fish skin gelatin incorporated with essential oils of ginger, turmeric, and plai, where they showed higher antioxidant activity than the control film. Perdonés *et al.* (2014) reported that chitosan films containing cinnamon leaf oil also exhibit higher antioxidant activity. Ruiz-Navajas *et al.* (2013) also developed chitosan films introducing *Thymus piperella* oil presented higher antioxidant activity than edible films containing *Thymus moroderi* essential oil. The antioxidant activity hence depends upon the nature of essential oils and the structural features of the molecules, mainly the reactivity of the hydroxyl groups of the compounds. Concentration, temperature, light, physical state of the system, substrate type, and microcomponents acting as pro-oxidants or synergism also impact the antioxidant activity. Ponce *et al.* (2008) reported that butternut squash containing chitosan coatings incorporated with oleoresins improves the antioxidative protection of the fresh-cut squash, limiting the browning process without adversely affecting their organoleptic acceptability. However, the addition of antioxidants to films not necessarily always improves the antioxidant efficacy. Indeed, Atarés *et al.* (2010) reported that incorporation of Cinnamon oil and ginger oils with sodium caseinate films does not enhance antioxidant effect as compared with the control film without essential oils, even though cinnamon oil alone show high antioxidant property. In addition to their high antioxidant property, essential oils can also strengthen the water barrier properties of the film because they display the hydrophobic nature of lipids (Atarés *et al.*, 2010; Kaliana *et al.*, 2014).

Extracts

Chemically synthesized antioxidants have raised some safety concerns and various regulatory agencies have already restricted their use as food additives, so researchers have focused on films incorporated with antioxidants from various natural extracts (Murcia and Martínez-tomé, 2001; De'nobili *et al.*, 2013; Ninja *et al.*, 2017; Paul, 2018). These extracts also contribute to nutritional and quality features without affecting the food product integrity (Guilbert *et al.*, 1996a,b).

Extracts like tea extracts (Das *et al.*, 2013; Li *et al.*, 2014), ginseng extract (Norajit *et al.*, 2010), fruit and vegetables extracts (Akhtar *et al.*, 2012; Supapvanich *et al.*, 2012), and tulsi extracts (Ninja *et al.*, 2017) possess tremendous antioxidant activity, can reduce lipid oxidation, and enhance the quality and storage life of various food systems. The antioxidant effect of these extracts results primarily due to phenolic compounds and their antagonistic, synergistic, and additive effects (Krochta and Mulder-Johnson, 1997). However, despite their excellent scavenging effect and ability to protect the food products, they are still less effective than synthetic antioxidants.

Several studies on antioxidant and functional extracts that also confer color to edible films have been published (Gómez-estaca *et al.*, 2009a,b; Norajit *et al.*, 2010; Akhtar *et al.*, 2012; Li *et al.*, 2014). In addition, it has been well established that extracts exhibit coloring and antioxidant properties that enables effective control against photo-oxidation by reduced light transmission, especially ultra violet radiation (Norajit *et al.*, 2010; Li *et al.*, 2014). Hence, in the same way that natural extracts were successfully incorporated into edible coatings and films. Their use in edible films and coatings in fruits and vegetables could maintain food quality and also extend the shelf life. However, light exposure may degrade the active compound during storage and deteriorate optical properties like luminosity or chroma. Nevertheless, several scientists including the author of this article have shown that this technology can better control weight loss, color, nutrient loss and respiration rates, allowing for longer shelf life as compared with control samples (Pastor *et al.*, 2011; Das *et al.*, 2013; Kaliana *et al.*, 2014; Ninja *et al.*, 2017; Paul *et al.*, 2018; Paul, 2018).

Nanomaterials

Incorporation of nanomaterials into other base materials exhibit modifications in the properties of the materials and impart novel properties to the materials. In order to achieve these modifications in films and coatings, a proper interaction between the polymeric base and the nanofiller is desired (Lagaron and Lopez-Rubio, 2011).

Impregnation of the filler into the polymeric matrix can be achieved using in situ polymerization (dissolution of the nanoparticles in the monomer solution before polymerization), solvent intercalation (use of a solvent to increase the affinity between the nanoparticles and the polymer) and melt intercalation (addition of particles during the preparation of formulation for extrusion) (Chivrac *et al.*, 2009). When the affinity between the nanoparticles and the polymer is low, the nanoparticle or nanoclay interlayer does not expand and the nanostructures or clay tactoids remain as such in the polymeric base. In this way, no true nanocomposite can be formed. When the affinity between the nanostructure and the polymer is moderate, the polymer can partly penetrate the clay interlayer, leading to an intercalated structure, which is still a layered structure. When the affinity is high, an

exfoliated structure is formed by dispersion of the nanostructures into the polymeric base (Arora and Padua, 2010; Chivrac *et al.*, 2009; Paul, 2018). Since a high surface-to-volume ratio has the enhanced effect on the attributes of the developed polymer, the exfoliated structure is the ultimate goal.

Various chemical modifications on nanostructure surface in order, such as cationic exchange, use of block copolymers adsorption, ionomers, and organosilane grafting, are sometimes necessary to make the surface more hydrophobic leading to intercalation/exfoliation in the polymer matrix. Modification of the polymer can also lead to a more homogeneous dispersion (Chivrac *et al.*, 2009; Arora and Padua, 2010; Silvestre *et al.*, 2011).

Other strategies

Another way to enhance the performance of edible packaging is by chemical and/or physical modification of the polymers. Modification can impart a positive effect on mechanical properties and water vapor permeability of the produced film. It can also be used as a tool to enhance compatibility between two polymers or even polymers and additives. Towards this objective, mainly starch from different sources has been modified to improve their hydrophobicity, making them more compatible with hydrophobic functional additives and other polymers or food surfaces.

Oxygen permeability and hydrophobicity of microfibrillar cellulose (MFC) films was found to be improved by acetylation with acetic anhydride. Film thicknesses from 42 to 47 μm lead to oxygen permeability values required for MAP application (Rodionova *et al.*, 2011). Flexible starch films with water resistant properties can be produced by heating gelatinized starch with lithium chloride in an anhydrous suspension in the presence of an organic solvent (Fang *et al.*, 2005).

Cross-linking of cellulose acetate with tri-sodium tri-meta phosphate led to materials with higher tensile strength, lower water absorption and slower degradation kinetics (Demirgöz *et al.*, 2000). Crosslinked starches are more hydrophobic because it has additional carbon chains than native starches. This causes better compatibility of the starch with other polymers or additives (Kim and Lee, 2002).

According to Gennadios *et al.* (1993), water vapor permeability and oxygen barrier properties of a wheat gluten film can be improved by partial substitution of the wheat gluten with hydrolyzed keratin, probably due to bonding between the two proteins. Better water vapor resistance property was also demonstrated by soaking wheat gluten film in CaCl_2 solution and then in distilled water or in a neutral solution. This treatment process also showed enhanced tensile strength and is probably due to cross-linking of Ca^{2+} in the film structure and protein insolubility of wheat gluten at a pH equal to the isoelectric point. Further, Rhim *et al.* (1999) demonstrated that irradiation with ultra violet light on wheat gluten based film increases the tensile strength by 20%, suggesting a probable cross-linking within the film composition.

Regulatory Status

At global level, proper regulation for edible films and coatings, especially their additives and their quantum to be used is lacking. However, some countries have introduced few points in their own food safety regulations to keep the application of edible films and coatings within the safety limits. European Directive and USA regulations consider edible films and coatings as food ingredients, food products, food additives food packaging materials or food contact substances (ED European Parliament and Council Directive No95/2EC, 1995).

In Europe, the substances that can be incorporated into edible coating formulations are mainly considered as food additives and are listed in the list of food additives for general purposes, although acacia, pectins, karaya gums, polysorbates, beeswax, fatty acids, and lecithin are mentioned specifically for applications in edible films and coating (ED European Parliament and Council Directive No95/2EC, 1995). In any case, the use of these film or coating forming ingredients is allowed, provided that the "quantum satis" principle is observed. This Directive was complemented by the introduction of specific purity criteria for food additives.

In most of the countries, chemical substances used as antimicrobials are regarded as food additives, only if the primary purpose of the substances is to extend the shelf life. Another important domain of concern within regulatory status is the presence of allergens. Many edible films and coatings are made with the substances that could cause allergic reactions among certain individuals. Several edible films and coatings are also made from whey protein, casein, gluten, soy protein and peanut protein (Rojas-Graü *et al.*, 2009). So, the presence of a known allergen in edible packaging of food including fruits and vegetables must also be clearly labeled.

Further, edible films and coatings are meant for the purpose of its direct consumption, hence proper regulations for the compositions of edible films and coatings should be formulated and each and every ingredient should be properly labeled. Looking into the research outputs provided by various researchers, uses of organic, inorganic or biological nanomaterials are also being emphasized by business communities. Safety of consumption of nanomaterials and other chemically modified substances could not be assured till date. However, business communities may also adopt fraudulent means to incorporate potentially harmful substances through the gaps within the regulations. As the application of edible films and coatings are increasing continuously, therefore the regulatory authorities of every country should take the matter seriously into their notice and frame a proper regulation so that the goodness of the technology can be adopted eliminating any immediate or future safety issues among the consumers.

Future Trends

Edible films and coatings are very promising technologies for the future improvement in post harvest management, storage and packaging of fruits and vegetables. Indeed, they could be used where petroleum based packaging cannot be used, like – they can separate several compartments within a single food products if needed. Edible packagings can also be fabricated and utilized as *intelligent packagings* because they can be both active, selective and also be incorporated with smart features for infinite potential use.

A new generation of edible coatings for climacteric and perishable fruits and vegetables is under development, with the aim of allowing the incorporation and/or controlled release of functional compounds using micro-level and nanotechnological solutions such as nanoencapsulation and multilayered coatings, thus enhancing their viability and stability. Alginate is the most widely used biopolymer for encapsulation, but materials from different other biological sources can also be used. Enzymes, antioxidants, antimicrobials, colorants, flavors, probiotic, prebiotic, essential oils (omega-3-fatty acids) are among the most applied functional substances in encapsulations.

Nowadays, nanotechnologies are being used to enhance the nutritional aspects of food by means of nanosized additives and nutrients and nanolevel delivery systems for functional compounds. The concept of nanocomposites further brought a stimulating route for creating new and innovative materials, also with natural polymers. Coating foods with nanolaminates involves entirely either food-grade ingredients (proteins, polysaccharides, lipids) or could also include various functional materials such as anti-microbials, antioxidants, antibrowning agents, enzymes, colorants and flavorings. Further, the electrodeposition technique has also demonstrated potential that could be used to coat highly hydrophilic food including fruits and vegetables surfaces such as fresh-cut fruits and vegetables.

Consumer demands are driving the global scientists to search for alternatives to synthetic packaging materials with cost effectiveness. However, it is observed that the cost of edible films and coatings is many folds higher than those of polyethylene or polypropylene film. However, their cost is not major hurdle to their development because quantities used are very low, and till now they are especially applied for very specific goals in value-added food products. Thus, the concept of edible polymers and that of synthetic materials should be used synergistically for the development of new scope and utility, new biodegradable and edible materials, and new environment friendly approaches with the primary objective of proper post harvest storage, packaging and transportation of agricultural and horticultural produce and also shelf life extension of fresh and processed food products.

Introduction

In 2016, the global industrial sector consumed 144 EJ final energy, which corresponded to 36% of global final energy consumption (based on IEA, 2018a). The International Energy Agency (IEA, 2018b) projects that without any further actions, by 2040, industrial energy use will increase to 206 EJ (or by 43%). Improved energy efficiency can limit industrial energy use and is considered as one of the most cost-effective ways of reducing greenhouse gas emissions (Ryan and Campbell, 2012). Although in the past decades the adoption of energy efficiency measures reduced industrial energy intensity, increased energy demand due to increased industrial production, has offset any energy gains from improved efficiency. With increasing industrial productivity, industrial energy use and associated greenhouse gas emissions are expected to grow further, increasing the importance of energy savings.

In this article we will first give an overview of past developments of energy use and greenhouse gas emissions in industries, where we look at trends in sectors and countries (Section “Energy Use and Greenhouse Gas Emissions in Industries”). In Section “Energy Efficiency Measures” we focus on four major energy consuming sectors (chemicals, iron and steel, cement and aluminum) and describe the main energy consuming processes and energy saving opportunities. Finally, conclusions are given in Section “Conclusions”.

Energy Use and Greenhouse Gas Emissions in Industries

Fig. 1 shows a breakdown of global energy use in industries by sector, based on IEA (2018c). The chemical sector (including petrochemicals) is the biggest sector and is responsible for 26% of industrial energy use in 2016. This sector is followed by the iron and steel sector, which accounts for 19% and non-metallic minerals and oil refineries which both consume 9% of industrial energy

Fig. 1 Global energy use in industries in 2016 (PJ). Based on data from IEA, 2018c. Extended World Energy Balances Database. 2018 ed. Paris: International Energy Agency (IEA).

use. Energy use in non-metallic minerals is mainly related to cement production, which accounts for 70%–80% of the sectors energy use (Kermeli *et al.*, 2019).

Out of the energy carriers, coal is most often used in industries with 28%, followed by oil (26%), natural gas (19%) and electricity (18%). Renewable energy use, excepting biomass, is negligible so far. Coal is mainly used in the iron and steel sector (78% of total coal use in industries) and non-metallic minerals (19%), followed by chemicals (10%). Natural gas is more spread over all sectors, with its main use in chemicals (37%). Oil use is mostly occurring in chemicals (47%) and oil refining (24% of total oil use). Electricity use is also widely spread but highly consuming sectors are chemicals (14%), iron and steel (13%) and non-ferrous metals (12%). The energy use in the non-ferrous metals sector is for about 70% related to aluminum production (Kermeli *et al.*, 2015).

If we add up all sectors the total energy use in industries amounted to 174 EJ in 2016, which is 30% of total primary energy use worldwide (576 EJ). This includes:

- (1) 144 EJ final energy use; of which 30 EJ is non-energy use (consisting for 26 EJ of feedstocks in petrochemicals),
- (2) 14 EJ of energy use and transformation losses in coke ovens and blast furnaces and
- (3) 15 EJ of energy use in oil refineries.

Indirect energy use from electricity consumption that is not produced on site is not included.
